The weight of this muscle increased after denervation⁵, the average weight of the denervated muscles being 15.8 ± 1.5 mg. which was 48% greater than for innervated muscles (10.7± 1.0 mg; $P \ll 0.001$, n = 32). Consequently, the difference in ³H-QNB binding between the innervated and denervated muscles was exaggerated when expressed as amount bound per whole muscle. The total ³H-QNB bound by the denervated muscles was 1.98 ± 0.15 fmol per muscle and this was 2.1 times the amount bound by the innervated muscle (0.90±0.08 fmol per muscle).

The effectiveness of sympathetic denervation procedures was verified in several animals by fluorescence histochemistry. Stretch preparations of glyoxylic acid-treated muscle showed a dense innervation of the normal muscle but almost complete absence of fibres in the denervated tissue. Occasionally a few regenerating fibres were observed at the edge of the muscle.

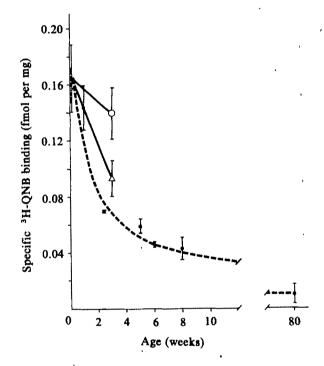

Fig. 1 Effect of denervation on the muscarinic receptor population of the developing chicken secundariorum muscle. The muscarinic receptor population of unoperated chicks at various ages (broken lines) is compared with that of chicks denervated unilaterally at 1 day old and killed 3 weeks later (solid lines). The open circles indicate the ³H-QNB bound by denervated muscles, and the open triangles the contralateral, control muscles. Denervation of the muscle was performed unilaterally by cauterization of the nerve 1 cm from its entry into the muscle. Three weeks after denervation, muscles were excised and homogenized with a glassglass hand homogenizer (Wheaton Scientific) in 1.5 ml of 50 mM phosphate buffer, pH 7.4. After centrifugation at 18,000g for 4 min, pellets were resuspended in 5 or 10 volumes of buffer. Triplicate 200-µl samples were incubated at 37 °C for 1 h with ³H-QNB (1 nM, NEN) in a total volume of 240 µl. Incubation was terminated with the addition of 1 ml of buffer and centrifugation for 4 min at 18,000g. Following two buffer washings, pellets were resuspended in 200 µl of distilled water, added to 15 ml Triton X-100/toluene scintillation cocktail and counted in a Searle Nucleonics β -spectrometer at an efficiency of ~40%. As 10-20 mg wet weight of original muscle were required for each determination, it proved necessary to pool varying numbers of muscles. Each point represents a minimum of 11 individual determinations, and is expressed as the mean ± s.e.m. All statistical values were obtained using a two-tailed Student's t-test.

Several radioligands have been used to estimate muscarinic binding sites in brain⁷, sympathetic ganglia⁸ and smooth muscle^{3,4}. These studies have indicated that the use of radiolabelled muscarinic antagonists and in particular 3H-quinuclidinyl benzylate results in binding to a single site that is accepted as the muscarinic receptor. Our previous studies with the expansor secundariorum have shown that the binding characteristics of the radioligand in this tissue are similar to those observed in other tissues, saturation occurring at 0.6 nM and with a K_D of 0.089 nM¹. We have therefore used the binding of ³H-QNB to muscle membrane as a measure of the muscarinic receptor population.

Trophic regulation of skeletal muscle function has long been the subject of intensive investigation^{9,10}. In contrast, few studies have examined the trophic effect of autonomic innervation on smooth muscle function. Indeed, until recently there has been little evidence that postganglionic sympathetic fibres exert a trophic influence on their effector cells. Unlike skeletal muscle, smooth muscle demonstrates a remarkable degree of autonomy. In particular, atrophy does not occur following denervation but functional integrity is retained.

Our results provide strong evidence for a trophic regulation of smooth muscle function by sympathetic nerves. Prevention of the normal loss of ³H-QNB binding sites from the developing expansor secundariorum by denervation suggests that their production is normally repressed by a mechanism of neuronal origin that is likely to be mediated by transmitter molecules, specific trophic molecules or electrical activity within the muscle. Whether the low level of muscarinic receptors in this tissue has any function in the young animal has not been

The composition of the nerve supplying the expansor secundariorum has not been fully established. Although it is clear that there is a dense adrenergic innervation of the muscle¹ information has been presented concerning a sensory input. Nerve stimulation has been shown to cause muscle contraction via noradrenaline release, with no evidence of acetylcholine release². These studies clearly show that the nerve regulates the muscarinic receptor population, but do not demonstrate whether this regulation is mediated by noradrenergic fibres, sensory fibres or other as yet unidentified nerve types. The evidence against the involvement of cholinergic nerves is not conclusive, but makes it unlikely that acetylcholine is involved. Histochemical and biochemical analyses over the entire developmental period are necessary to exclude this possibility. Further studies examining the origin of the nerve supply to this muscle would also aid in assessing the factor or factors involved in the regulation of the muscarinic receptor population.

Finally, the presence of a discrete nerve supply and tendon to the expansor secundariorum, together with the results of the present study, suggests that this unique muscle will be a useful tissue in which to study the interaction between smooth muscle and its innervation.

Chronic continuous administration of neuroleptic drugs alters cerebral dopamine receptors and increases spontaneous dopaminergic action in the striatum

K. Murugaiah, A. Theodorou, S. Mann, A. Clow, P. Jenner & C. D. Marsden*

University Department of Neurology, Institute of Psychiatry and King's College Hospital Medical School, Denmark Hill, London SE5 8AF, UK and Agricultural Research Council, Institute of Animal Physiology, Babraham, Cambridge CB2 4AT, UK

The 'dopamine hypothesis' of schizophrenia states that the illness is due to overactivity of dopamine mechanisms in the brain. This hypothesis is based on two facts: (1) drugs, such as amphetamine, that enhance dopaminergic neurotransmission in the brain, may occasionally provoke a schizophrenic psychosis; and (2) acute administration of neuroleptic drugs, which are used to treat schizophrenia and other psychotic illnesses, causes blockade of brain dopamine receptors and initiates a chain of compensatory events which attempt to overcome such an action. We have previously shown that administration of neuroleptic drugs to rats for up to 18 months produces unexpected effects^{1,2}: after 6 months, all signs of blockade of dopamine receptors in the striatum have disappeared, and thereafter striatal dopamine receptors increase in number and become behaviourally supersensitive to administered dopamine agonists such as apomorphine. We now show that such chronic exposure to neuroleptics completely alters other characteristics of striatal dopamine receptors, and that in the intact animal, these changes are associated with spontaneous overactivity of striatal dopaminergic mechanisms. Unless other dopaminergic brain areas, for example in the mesolimbic or mesocortical regions, react differently from the striatum, the mode of action of neuroleptics, and the dopamine hypothesis of schizophrenia, may have to be reconsidered.

We first investigated the changes in the biochemical characteristics of striatal dopamine receptors which take place during 12 months' continuous administration of the neuroleptic trifluoperazine dihydrochloride to rats in two separate experiments-in one of them the drug was subsequently withdrawn and the animals were followed for a further 6 months (Fig. 1). The characteristics of striatal dopamine receptors were examined in these animals by estimating ³H-spiperone (0.125-4.0 nM) binding to striatal homogenates, the specificity of binding to dopamine receptors being defined by incorporation of dopamine $(10^{-4} \,\mathrm{M})$. After the first 3 months of trifluoperazine treatment there was a progressive increase in the number of striatal dopamine receptor binding sites (B_{max}) for ³H-spiperone binding in the drug-treated animals, compared with the agematched controls. B_{max} continued to increase until administration of the drug ceased after 1 yr; the number of striatal dopamine receptors then began to revert towards control levels after 3 months' drug withdrawal, and had reached control values after 6 months' drug withdrawal.

Receptor affinity, as judged by the dissociation constant (K_d) for ³H-spiperone binding to striatal tissue homogenates, also changed during 1 yr administration of trifluoperazine. In the first 3 months, K_d increased, as predicted because of the presence of drug in the tissue analysed, but after 6 months of drug administration K_d had completely or partially reverted to control levels. Thereafter, in both experiments, K_d progressively

^{*} To whom correspondence should be addressed

rose again, until the drug was withdrawn, when it abruptly reverted to control values. These changes could be explained if the drug levels had fallen, despite continued administration, perhaps due to enzyme induction, but this would not explain why K_d rose again between 6 and 12 months of trifluoperazine administration. In any case, measurement of the plasma concentration of the drug showed a gradual increase throughout this period of administration (G. Watkins, R. Whelpton and S. Curry, personal communication). The change in striatal dopamine receptor affinity after 6 months of trifluoperazine intake occurred simultaneously with the increase of dopamine receptor numbers (B_{max}) , suggesting that a new population of dopamine receptors of higher affinity than normal might have appeared; but a Hill plot of the data for 3H-spiperone binding to striatal homogenates did not deviate from unity. Whatever the reason for the change in the characteristics of striatal dopamine receptors after 6 months of trifluoperazine administration, and we can offer no explanation, the change

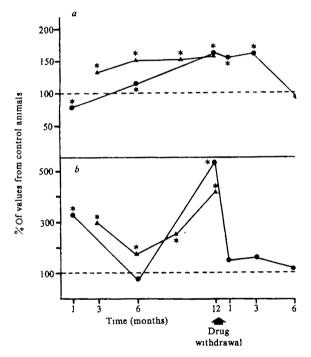

Fig. 1 Comparison of the alterations in dopamine (10⁻⁴ M)-specific ³Hspiperone (0.125-4.0 nM) binding to rat striatal preparations produced by the administration of trifluoperazine dihydrochloride continuously for up to 12 months in two distinct studies a, Receptor numbers (B_{max}) ; b, dissociation constant (Kd). The experimental groups were as follows. Expt 1: ● male Wistar rats (initial weight 200±12g; Olac International) received trifluoperazine dihydrochloride (2.5-3.5 mg per kg per day, Smith, Kline and French) for up to 12 months when the drug was withdrawn. Expt 2: A: male Wistar rats (initial weight 176±4 g, Bantin and Kingman) received trifluoperazine dihydrochloride (4.5-5 6 mg per kg per day) for up to 12 months. In each case a group of age-matched control animals from the same supplier received distilled water alone and was maintained alongside the drug-treated animals. At intervals during the course of the experiments, striatal preparations from drug-treated and control animals were examined for dopamine (10⁻⁴ M)-specific ³H-spiperone (26 Cl , Amersham) binding, according to the method of Leysen et al. Rats from age-matched control and drug-treated groups (n = 7) were killed by cervical dislocation and decapitation and the brain rapidly removed and placed on ice. The paired corpora striata were removed and placed in ice-cold 50 mM Tris buffer pH 7.7. Specific binding of 0 125-4.0 nM ³Hspiperone, as defined in the presence and absence of 10-4 M dopamine, was determined in triplicate on the pooled striatal tissue from both groups The data obtained were subjected to Scatchard analysis to determine the number of binding sites, expressed as pmol per g wet weight of tissue (K_d) , and the dissociation constant (K_d) . Statistical analysis of the receptor binding data was carried out using linear regression analysis of the results for drug-treated and control animals, which were compared using a twotailed Student's t-test *P<0.05. For comparison of the dissociation constant (K_d) and receptor numbers (B_{max}) in different animal groups at different time intervals, values in drug-treated animals are expressed as a percentage of K_d and B_{max} values in tissue from control animals obtained on the same day and assayed in parallel throughout the experiment.

Table 1 The effect of continuous administration for 14 months of distilled drinking water containing cis-flupenthixol (0 8-1.2 mg per kg per day), compared with distilled drinking water alone, on apomorphine-induced stereotyped behaviour and striatal acetylcholine concentrations in rats

Drug treatment (mg per kg per day)	Stereotypy score	Striatal acetylcholine (µg g ⁻¹)
Controls (distilled	2 ± 0 (6)	4.1 ± 0.3 (8)
water alone) cis-flupenthixol (0.8-1.2)	$3.9 \pm 0.1 * (6)$	$7.4 \pm 0.7^*$ (8)

Male Wistar rats (unitial weight 200 ± 12 g, Olac International) received cisflupenthixol hydrochloride (0 8–1.2 mg per kg per day; Lundbeck) for 14 months. A group of age-matched controls receiving distilled water alone was maintained alongside the drug-treated animals. Apomorphine-induced (0 5 mg per kg subcutaneously 15 min previously; Macfarlan Smith) stereotypy was assessed according to the scale: 0=normal; 1=continuous locomotor activity, discontinuous sniffing; 2=continuous sniffing; 3=discontinuous biting, licking and gnawing, 4 = continuous biting, licking and gnawing¹² The results are expressed as the mean (±1 s e.m.) for six animals in each group. Acetylcholine levels were determined by bioassay The caudate muclei of treated and control rats were rapidly dissected from the brain and homogenized in 1% acetic ethanol (1 ml glacial acetic acid in 99 ml absolute ethanol) and stored at -70 °C until required. Each sample was removed from the deep freeze and rotary evaporated to dryness 4 ml of frog Ringer were added to the extract and the pH was adjusted to 3.0 where necessary. The extract was then assayed on the eseminzed frog rectus using the method of Chang and Gaddum¹³, more recently described by Hebb and Silver14. Samples of the extract were compared with standard solutions of acetylcholine. A quantity of boiled alkali-treated sample equal to that of the unknown was added with each standard 15 to destroy the acetylcholine, and the addition of this as a control ensured that any substances (such as potassium) in the sample capable of causing a contraction of the rectus were not assayed as acetylcholine. To sensitize and stabilize the muscle preparation, 0.5 mg of Na-ATP was added with each sample and standard to the muscle bath. The assay used in this way was accurate to within 10%. Values in parentheses give the number of

observations.

* P < 0.05 compared with control animals, a two-tailed Student's t-test was used for parametric data; Mann-Whitney U-test was used for non-parametric results.

coincided with the onset of a behaviourally supersensitive response by the rats to the administration of dopamine agonists.

In the second series of experiments rats received cis-flupenthixol hydrochloride continuously for periods of up to 18 months. These animals demonstrated the same changes in B_{max} and K_d for specific binding of ³H-spiperone to striatal preparations. K_d initially increased, then reverted towards control levels at around 6 months, only to increase again by 12-18 months of drug intake (data not shown). At 18 months, prolonged neuroleptic intake had not only caused an increase in the number of striatal dopamine receptors, but also altered the relative sensitivity of the animals to the behavioural effects of dopamine agonists and antagonists. Whereas administration of apomorphine hydrochloride (0.125-1.0 mg per kg subcutaneously) to animals receiving such neuroleptic treatment resulted in an enhanced stereotyped response compared with age-matched controls, administration of an acute dose of trifluoperazine dihydrochloride (1-8 mg per kg intraperitoneally) produced less catalepsy in cis-flupenthixol-treated animals than in the control group (Fig. 2). Thus after 18 months' intake of cis-flupenthixol, the animals appeared to possess an increased number of striatal dopamine receptors that were supersensitive to the behavioural effects of dopamine agonists, but subsensitive to the effects of dopamine antagonists.

These results indicate that chronic neuroleptic administration alters the characteristics of striatal dopamine receptors as measured *in vitro* by receptor binding techniques, or as challenged by dopamine agonists and antagonists in behavioural pharmacological experiments. The crucial issue, however, is whether such changes are functionally significant in the intact animal or human patient.

To test this possibility, we have studied the effect of chronic neuroleptic intake on striatal acetylcholine activity. The post-synaptic striatal dopamine receptor lies, at least in part, on the cell body of cholinergic neurones, on which dopamine exerts inhibitory control^{3,4}. Alteration of striatal dopaminergic function affects acetylcholine activity. The acute administration of

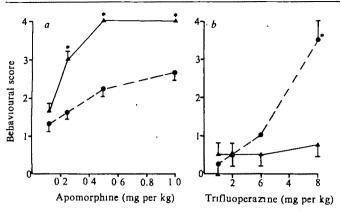

Fig. 2 Dose-response curves for a, the induction of apomorphine-induced stereotypy, and b, trifluoperazine-induced catalepsy in rats $(-\Delta -)$ receiving cls-flupenthixol (0.8-1.2 mg per kg per day) for 18 months, compared with control animals receiving distilled water alone $(--\Phi -)$. Male Wistar rats (initial weight 200 ± 12 g; Olac International) received cis-flupenthixol hydrochloride (0.8-1.2 mg per kg per day; Lundbeck) for 18 months. A group of age-matched control animals receiving distilled water alone was maintained alongside the drug-treated animals. Stereotypy induced by apomorphine (0.125-1.0 mg per kg subcutaneously 15 min previously; Macfarlan Smith) was assessed as described in Table 1 legend. The results are expressed as the mean (±1 s.e.m.) for six animals in each group. Catalepsy induced by trifluoperazine dihydrochloride (1-8 mg per kg intraperatoneally 3 h previously; SKF) was assessed as the time a rat maintained its front paws over a metal bar 2 cm in diameter and 7 cm from bench level and was scored according to the scale: 0-9 s = 0; 10 s-2.5 min = 1; 2.6-5 min = 2; 5.1-10 min = 3, 10.1-20 min = 4; >20 min = 5. The results are expressed as the mean (± 1 s e.m.) for six animals in each group. *P < 0.05 compared with control animals using a Mann-Whitney U-test for non-parametric data

neuroleptics decreases the content of acetylcholine in the striatum, due to an increased use of acetylcholine in active cholinergic neurones⁵⁻¹¹. If chronic neuroleptic administration causes a functional reversal of initial dopamine receptor blockade in the intact animal, the striatal acetylcholine content should increase, due to a decrease in cholinergic activity resulting from enhanced dopaminergic inhibition of striatal cholinergic neurones.

We produced striatal dopamine receptor supersensitivity in rats by the continuous administration of cis-flupenthixol for 14 months and examined changes in striatal acetylcholine content in the same animals. At the end of 14 months treatment with cis-flupenthixol, the rats exhibited an enhanced behavioural response to the dopamine agonist apomorphine, and basal striatal acetylcholine content had doubled (Table 1). This result suggests that after chronic cis-flupenthixol treatment, not only was the response of striatal dopamine receptors to an exogenous dopamine agonist no longer antagonized, but also the receptors were overactive in the intact animal. In other words, the chronically neuroleptic-treated rat striatum exhibited spontaneous dopaminergic synaptic overactivity.

In conclusion, chronic neuroleptic intake by rats for periods of up to 12-18 months changes fundamentally the character of striatal dopamine receptors, which increase in number, but also exhibit unexplained alterations in their affinity. Such changes are associated with parallel alterations in the response of the animals to exogeneous dopamine agonists and antagonists. In addition, and most important, there are also changes in striatal acetylcholine function which suggest that the spontaneous activity of at least some striatal dopamine receptors is increased in the chronically neuroleptic-treated animal. These events may be responsible for the emergence of tardive dyskinesias in man, and they must be taken into account when considering the mechanism of action of neuroleptics and the pharmacological basis of schizophrenia.

This study was supported by the Wellcome Trust, MRC and the Research Funds of the Bethlem Royal and Maudsley Hospital and King's College Hospital. We thank Smith, Kline and French and Lundbeck for generous drug supplies.

Specific non-opiate binding sites for human β -endorphin on the terminal complex of human complement

L. Schweigerer*, S. Bhakdi† & H. Teschemacher*

* Rudolf Buchheim-Institut für Pharmakologie and † Institut für Medizinische Mikrobiologie der Justus Liebig-Universität Gießen, Frankfurter Strasse 107, D-6300 Gießen, FRG

The opioid peptide β -endorphin is released from the pituitary into the blood under physical or emotional stress; its target tissues, however, are unknown¹. We report here the specific binding of human β -endorphin to both terminal complexes of human complement: the cytolytic, membrane-derived C5b-9(m) complex and the cytolytically inactive, serum-derived SC5b-9 complex. Binding is through the carboxy-terminus of B-endorphin rather than the amino-terminus, which is implicated in binding to opiate receptors. It is conceivable that the binding of β -endorphin to complement has physiological relevance in the adaptation of the immune system to stress

Human serum or plasma drawn in 10 mM EDTA was obtained from healthy donors. The complement pathway was activated by adding 2 g crushed inulin (Merck) to 100 ml serum followed by incubation at 37 °C for 4 h. Activation by inulin leads to the formation of the macromolecular, non-cytolytic SC5b-9 complex (comprising of complement components C5b, C6, C7, C8, C9 and the S-protein²). Supernatants obtained after centrifugation of the inulin-serum suspension were used directly in binding experiments or served as a starting material for the isolation of the SC5b-9 complex^{2,3}. The terminal, cytolytic complement complex, C5b-9(m), which consists of complement components C5b to C9 without the S-protein, was generated on target sheep erythrocyte membranes by lysis of the antibody-coated cells with human serum, and then isolated from detergent solubilizates of the membranes as described previously⁴. Detergent-solubilized, hypotonically lysed sheep

erythrocyte membranes served as controls.

125I-labelled β -endorphin was obtained by iodinating human B-endorphin (Bachem) using published techniques^{5,6}. Binding of human β -endorphin to the terminal C5b-9 complexes was demonstrated in a radioreceptor assay and by sedimentation analysis in sucrose density gradients.

In the radioreceptor assay, a small amount of human ¹²⁵I-\(\beta\)endorphin was found to bind to one or several components of native human serum (Fig. 1). After inulin activation, however, binding increased considerably (Fig. 1).

When ¹²⁵I-β-endorphin was incubated with native serum or with EDTA-plasma and the samples were then centrifuged through linear sucrose density gradients, total radioactivity was recovered in the top fractions of the gradient (not shown). In a parallel experiment using inulin-activated serum, however, ¹²⁵I-β-endorphin was also recovered in the fractions (22–23S) known to contain the SC5b-9 complement complex³.

The identity of SC5b-9 with a β -endorphin-binding component in inulin-activated serum was confirmed by the demonstration that purified SC5b-9 exhibited β -endorphin-binding capacity in the radioreceptor assay (Fig. 1). ¹²³I- β -endorphin also co-sedimented with isolated SC5b-9 in sucrose density gradients (not shown). Further experiments showed that human ¹²⁵I- β -endorphin was almost completely displaced from its binding sites on the SC5b-9 complement complex by unlabelled human β -endorphin (Fig. 1).

Saturable binding sites for human β -endorphin were also found on the SC5b-8 and SC5b-7 complexes of human complement, but not on the isolated C3 or C9 components (L.S., S.B.

and H.T., unpublished observations).

 125 I- β -endorphin also bound to the isolated, cytolytic C5b- 9 (m) complement complex, whereas no binding was observed to hypotonically lysed sheep erythrocyte membranes (radio-receptor assay data are shown in Fig. 1). Consistent with this finding, total radioactivity was recovered from the top fractions of density gradients when β -endorphin binding to control mem-

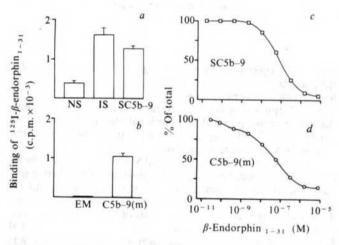

Fig. 1 a, b, Binding of human $^{125}\text{I-}\beta$ -endorphin₁₋₃₁ (c.p.m.) to native human serum (NS); inulin-activated serum (IS); the cytolytically inactive, terminal complex of human complement (SC5b-9); control erythrocyte membranes (EM); and the terminal, cytolytic complex of human complement [C5b-9(m)]. Mean values \pm s.d. from three determinations. c, d, Binding of human 125 I- β -endorphin₁₋₃₁ to the terminal SC5b-9 or C5b-9(m) complexes of human complement in the presence of various concentrations of unlabelled human β -endorphin₁₋₃₁ (binding expressed as per cent of total binding, specific plus nonspecific, as determined in the absence of β -endorphin₁₋₃₁; 100% corresponds to the binding values for SC5b-9 or C5b-9(m), respectively, shown to the left). Binding was determined by radioreceptor assay (a modified radioim-munoassay technique^{5,6}): 150 µl buffer (0.02 M sodium phosphate, 0.15 M NaCl, 0.01% bovine serum albumin (BSA), 0.1% gelatin, 0.01% thiomerosal, pH 7.5) were incubated with 50 µl serum or 50 µl complement complex or membrane solution (adjusted to 300 or 30 µg protein per ml buffer for displacement or saturation binding experiments respectively) and with 20 μ l buffer containing 125 I- β -endorphin and 0.1% Triton X-100. In addition, 20 µl buffer containing 0.1% Triton X-100 were added; in the competition experiments, the buffer also contained unlabelled inhibitor. Total concentration of 125 I- β -endorphin in radioreceptor assays was adjusted to ~8,000 c.p.m. per tube corresponding to 0.35 nM. The samples were incubated at 4 °C for 18 h. Then 300 µl of ice-cold charcoal suspension (1 g charcoal and 0.5 g BSA in 100 ml buffer) were added to adsorb free labelled or unlabelled ligands. After 10 min incubation at 4 °C the samples were centrifuged and the radioactivity in the supernatants was measured as an indication of the amount of ¹²⁵I-β-endorphin bound to complement complex.

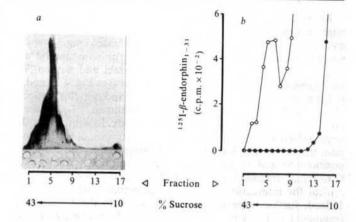

Fig. 2 Binding of human ¹²⁵I-β-endorphin₁₋₃₁ to C5b-9(m) demonstrated by co-sedimentation in a sucrose density gradient. a, Fused rocket immunoelectrophoresis²² (using a specific antiserum to identify C5b-9(m) complex) from fractions of density gradient centrifugation of a sample containing C5b-9(m) complex. b, Radioactivity determined in the fractions from a density gradient centrifugation of samples containing $^{125}I-\beta$ -endorphin incubated with either C5b-9(m) complex (O) or detergent-solubilized control erythrocyte membranes (). No radioactivity sedimented in the control experiment. In the experiment performed with C5b-9(m) complex, however, the radioactivity peak coincided with the peak of immunoprecipitate; no protein was found in the upper fractions (9-13) of the gradient, indicating that the radioactivity in these fractions reflects ^{125}I - β -endorphin dissociated during centrifugation. For density gradient centrifugation 50 µl 12 I-B-endorphin solution (4 nM) were incubated at 22 °C for 20 min with either 250 µl inulin-activated serum or SC5b-9 or C5b-9(m) complex, or, as controls, with saline, EDTA-plasma or erythrocyte membranes. Samples were then centrifuged at 8 °C through 12.4 ml linear 10-43% (w/v) sucrose density gradients (containing 25 mM Tris buffer, 50 mM NaCl, 5 mM NaN3, 2.4 mM Triton X-100, 2.5 mM DOC pH 8.2) at 35,000 r.p.m. in a SW41 Ti rotor (Beckman L2 65 B) for 16 h (ref. 3). Fractions were collected from the bottom of the tube and assayed for radioactivity.

branes was tested (Fig. 2); however, on centrifugation of the C5b–9(m) complex incubated with 125 I- β -endorphin, radioactivity was also found in the fractions (25–40S) which contained the complex⁷ (Fig. 2). Figure 1 shows displacement of 125 I- β -endorphin from the C5b–9(m) complement complex by unlabelled β -endorphin.

To test the reversibility of the binding reaction, we performed chase experiments. Samples containing C5b–9(m) were incubated with ^{125}I - β -endorphin for 18 h at 4 °C. Subsequent addition of unlabelled β -endorphin resulted in a decrease of ^{125}I - β -endorphin binding providing evidence for the reversibility of ^{125}I - β -endorphin binding to the C5b–9(m) complex. The shapes of the displacement curves (Fig. 1d; Fig. 4) and a Scatchard analysis of binding data (Fig. 3b) suggested negative cooperativity or several classes of binding sites. Assuming two classes of binding sites, we calculated two corresponding $K_{\rm d}$ values from the Scatchard plot (Fig. 3b) of about 80 and 3 nM respectively; the latter was in reasonable agreement with a $K_{\rm d}$ of about 1 nM estimated from the binding curve of a saturation experiment (Fig. 3a).

Classical opiate receptors are known to bind the N-terminal fragment of β -endorphin: β -endorphin is displaced from these binding sites by opioid peptides such as Met- and Leuenkephalin, and by the opiate antagonist naloxone. None of these substances, in concentrations up to $10 \,\mu\text{M}$, was able to inhibit $^{125}\text{I}-\beta$ -endorphin binding to the C5b-9(m) complex. Thus the N-terminal fragment of β -endorphin is obviously not essential for the binding of human β -endorphin to the human complement complex C5b-9(m).

To determine which fragment of human 125 I-B-endorphin might interact with the C5b-9(m) complex, competition experiments were performed using several unlabelled fragments of human β -endorphin and camel β -endorphin as inhibitors (Fig. 4). The amino acid sequences of camel and human β endorphin differ only at positions 27 and 31 (see Fig. 4 legend). β -Endorphin₁₋₁₆, human β -endorphin₁₋₂₇ and camel β -endorphin₁₋₃₁ all failed entirely to compete with human ¹²⁵I-β-endorphin₁₋₃₁ in binding to the C5b-9(m) complex. In contrast, both human β -endorphin₁₋₃₁ and human β -lipotropin₁₋₉₁ which contains the amino acid sequence of human β -endorphin between positions 61 and 91, displaced $^{125}I-\beta$ -endorphin₁₋₃₁. Thus, the C-terminal fragment of human β -endorphin seemed to be critical for interaction between β -endorphin and C5b-9(m). Indeed, further experiments performed with the C-terminal fragment Lys-Gly-Glu of human β -endorphin showed that this tetrapeptide was capable of displacing ¹²⁵I- β -endorphin₁₋₃₁ from the C5b-9(m) complex (Fig. 4); however, the concentrations required were about 1,000-fold higher than those of human β -endorphin₁₋₃₁. All the data therefore support the existence of novel, non-opiate binding sites on the C5b-9(m) complex for the C-terminal fragment of β -endorphin. The relatively high concentrations of the C-terminal tetrapeptide required to displace ¹²⁵I-\(\beta\)-endorphin suggest that other regions of the peptide may also contribute to the binding.

The structural specificity of β -endorphin binding was further confirmed by the demonstration that $^{125}I-\beta$ -endorphin was not displaced from the C5b-9(m) complex by other peptides (10 μM) such as adrenocorticotropin₁₋₂₄, insulin, luteinizing hormone-releasing factor, dynorphin₁₋₁₃ or β -casomorphin₁₋₇. Human leukocyte interferon⁸ and IgG⁹ have been reported to interact with endorphin antisera; however, neither human fibroblast interferon nor IgG and its Fab or Fc fragments affected the binding of ¹²⁵I-\(\beta\)-endorphin to the C5b-9(m) complex.

The binding of human β -endorphin to the terminal C5b-9(m) complement complex thus exhibits several characteristics of a ligand-receptor interaction: reversibility, structural selectivity, saturability and high affinity; and it is tempting to assume that the process is biologically significant. Indeed recent results are consistent with an involvement of endorphins in the immune system: a transport system for benzomorphans in leukocytes has been reported¹⁰; opioids apparently influence plasma levels of interferon¹¹; α -endorphin-immunoreactive material has been detected in plasma cells¹²; and there is evidence for the

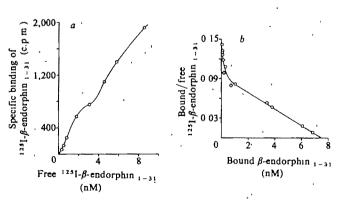

Fig. 3 a, Saturation experiment: Increasing concentrations of human 125 1- β -endorphin₁₋₃₁ were incubated with C5b-9(m) (6 μ g protein per ml) in the presence or absence of 1.7 μ M human β -endorphin₁₋₃₁. Free ¹²⁵I- β -endorphin was plotted against specifically bound (displaceable by 1.7 μ M unlabelled β -endorphin) ¹²⁵I- β -endorphin. Mean values from four determinations (s.d. ± <4%). Biphasic curves were obtained in several experiments. b, Scatchard analysis of binding data obtained by displacement²³ of human ¹²⁵I- β -endorphin by unlabelled human β -endorphin (Fig. 4). Specifically bound/free ¹²⁵I- β -endorphin is plotted as a function of total (labelled plus unlabelled) ligand specifically bound.

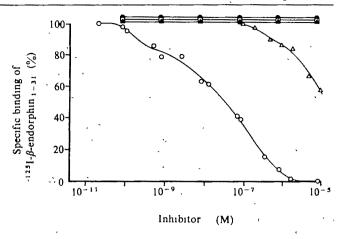

Fig. 4 Specific binding of human ¹²⁵I-β-endorphin₁₋₃₁ to C5b-9(m) in the presence of various concentrations of unlabelled binding inhibitors: \square , β -endorphin₁₋₁₆; \blacktriangle , human β -endorphin₁₋₂₇; \bullet , camel β -endorphin₁₋₃₁ (C-terminal amino acid sequence His-Lys-Lys-Gly-Gln); O, human β-endorphin₁₋₃₁ (C-terminal amino acid sequence Tyr-Lys-Lys-Gly-Glu); and Δ , human β -endorphin₂₈₋₃₁ (amino acid sequence Lys-Lys-Gly-Glu). Mean values from three determinations (s.d. \pm <4%). Specific binding represents bound ¹²⁵I- β -endorphin, that is displaced by 8.3 μ M unlabelled human β -endorphin₁₋₃₁.

presence of opioid receptors on phagocytic leukocytes¹³ and T lymphocytes^{14,15} as well as for non-opiate β -endorphin receptors on cultured lymphocytes¹⁶.

 β -Endorphin appears to be released from the pituitary into the blood under physical or emotional stress¹⁷⁻¹⁹ and during parturition^{20,21}. This might represent an adaptation of the immune system to stress situations.

We thank Margit Roth, Mechthild Vogel and Silvia Wilhelm for technical assistance, Professor Glossmann for valuable discussions, Dr Li for human β-lipotropin₁₋₉₁ samples and Dr Hofstetter for the gift of IgG and its Fab and Fc fragments. This study contains parts of the thesis of L. Schweigerer to be presented to the Fachbereich Humanmedizin in partial fulfilment of a doctorate of medical science. The work was supported by Deutsche Forschungsgemeinschaft (SP Neuroendokrinologie and grant We 340/10).

Parental exposure to X rays and chemicals induces heritable tumours and anomalies in mice

Taisei Nomura

Institute for Cancer Research, 1st Department of Surgery, and Department of Fundamental Radiology, Osaka University Medical School, Fukushima-ku, Osaka 553, Japan

Although radiation and various chemicals are known to produce mutations, there is a paucity of information on the production of germ-line mutations leading to heritable tumours and anomalies. I now report a significant and large increase in such tumours and anomalies following treatment of ICR parent mice with X rays and urethane. About 90% of the induced tumours were in the lung, and were inherited as if they were dominant mutations with about 40% penetrance.

X-ray irradiation was chosen because of the substantial previous experimental work on radiation mutagenesis ¹⁻⁶. Urethane is known to be mutagenic, carcinogenic and teratogenic in mice and has also been used widely as a human drug. Additional experiments, with similar results, were done with 4-nitroquinoline 1-oxide (4-NQO). The present report summarizes the data from large-scale experiments involving 12,905 live-born mice and 9,645 fetuses from 2,904 parents studied during 1967–81 (the spontaneous and induced rates of tumours and anomalies have not changed noticeably in this period). The experimental procedures and detailed results will be published elsewhere.

The first comparison between radiation and urethane was in the production of dominant lethals. As shown in Fig. 1, there was a significant, almost linear increase in dominant lethals following irradiation of spermatids and spermatozoa. Similarly, there was an increase of dominant lethals following treatment of mature oocytes, with no significant fractionation effect (although the data, taken at face value, suggest a slight reduction with fractionation). On the other hand, treatment of spermatogonia produced no significant increase, although the numbers are too small for a small change to be detected. These results are in accord with previous studies8-11. In contrast, examination of 5,830 embryos revealed no significant increase of dominant lethals from urethane treatment (1.5, 2.0 and 2.25 mg per g) at any stage. Nevertheless, as will be shown below, urethane is very effective in producing tumours and anomalies.

As shown in Table 1, there is a large and significant increase in anomalies in the progeny of parents treated with radiation or urethane. Generally, a higher rate of anomalies is detected prenatally than after birth, because many of the anomalies (for example, cleft palate, exencephalus, gastroschisis and buphthal-

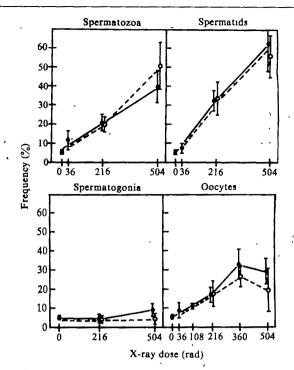

Fig. 1 Per cent of dominant lethals in the progeny of mice irradiated at the stages and dosages shown • Acute doses, O, fractionated doses, given in 36 rad amounts at 2-h intervals. Dominant lethals were measured by the mean number of early deaths per implant Vertical bars indicate the 90% confidence limits of the mean computed from the t distribution. For spermatozoa treatment males were mated 1-7 days after irradiation, for spermatid 15-21 days, and for spermatogonia 64-80 days; for mature occytes at the late follicular stage, females were irradiated 1-14 days before ovulation.

mus) are lethal shortly after birth. Only open eyelid, the predominant type among non-lethal anomalies, was shown to be transmissible (see Table 1 legend).

Figure 2 gives the dose-response data for radiation and the effects of dose-fractionation. The data are too limited to permit any conclusions about the shape of the dose-response relationship for male treatment, although there is a clear increase with dose in females. As with dominant lethals, the treatment of spermatogonia was less effective than post-meiotic treatment. There is again a suggestion of a fractionation effect for oocyte treatment.

Both radiation and urethane significantly increase the number of tumours in the progeny, regardless of which sex is treated (Table 1). The dose-response data for radiation (Fig. 3) show a clear increase with dose for treatment of post-meiotic stages in males and less clear results for spermatogonial treatment. Occytes at late follicular stages were resistant to 36-108 rad of X rays, but very sensitive to higher doses. Both the

[&]quot;X-ray irradiation was by Toshiba KC-18-2A, 180 KVp at a rate of 72 rad min⁻¹. Data are totals for various dosages, fractionations and age of exposure. Urethane was given as a single subcutaneous dose. Pathology was detected both by gross examination and histologically. The induced anomalies were cleft palate, kinky and/or short tall, dwarf, open eyelid, exencephalus, hydrocephalus, gastroschisis, polydactyly, syndactyly, gigantic toe, buphthalmus, hydatid mole, atresia hymenalis, mislobulation of lung or liver, and hemiplegia. Among non-lethal anomalies, open eyelid, the predominant type (41%), was transmissible to f_2 , but transmission of tail anomaly was inconsistent. Other non-lethal anomalies are sterile or too rare to examine exact heritability. Types of induced tumours are given in the text. Results were significantly different from the control value at $^*P < 0.001$, $^*P < 0.001$ and $^*P < 0.005$ by χ^2 .

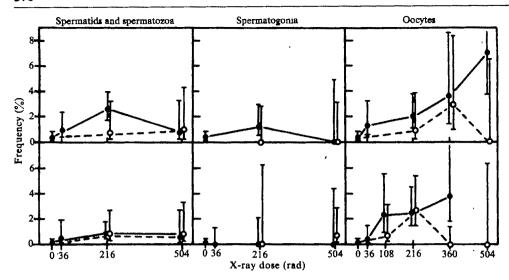

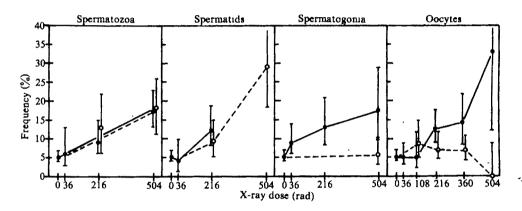

Fig. 2 Frequency of prenatal (above) and postnatal anomalies (below) in the progeny of parents irradiated in a single dose (●) and fractionated (○). Frequency of the anomaly was given by per cent of anomalous progeny in survivors. Vertical bars indicate 90% binomial confidence limits. For treatments, see Fig. 1 legend. Although data are not shown, spermatocytes at 22–42 days before mating were twice as sensitive to X rays as were post-meiotic sperm. Further study on dose-response relationship remains with these stages.

Fig. 3 Frequency of tumours in the progeny of mice irradiated at various stages and doses. • Acute doses; O, fractionated doses. Tumour frequency was given by per cent of tumour-bearing progeny in survivors. Vertical bars indicate 90% binomial confidence limits. For treatments, see Fig. 1 legend.

spermatogonial and oocyte treatment effects of dose-fractionation suggest some repair at high doses. Eighty-seven per cent of the induced tumours were in the lung (papillary adenomas), the remainder being of various types—ovarian tumour, lymphocytic leukaemia, stomach tumour, lipoma, granulosa cell tumour, thyroid tumour, liver haemangioma and hepatoma. The spectrum of tumour incidence in the offspring of treated animals is essentially the same as in controls (90% in the lung).

To confirm that the induced tumours are heritable, the F_1 progeny of treated parents were mated and their progeny examined. In addition to those tumours induced by urethane and radiation, some induced by 4-NQO were included. The mice were mated as young adults and the presence or absence of tumours was determined at 8 months of age. The progeny were then classified as to the retrospectively determined type of the parent. The data are shown in Table 2. In each case the original treated mouse was a male, as a precaution against the possible transmission of the chemical to the progeny. The results were confirmed by continuing the urethane-treated group into the F_3 generation. The F_3 results were: $+\times-$, 5/22; $-\times-$,

Table 2 Lung tumours in F2 progeny of treated parents

Phenotypes	Parental treatment		
of F ₁ parents	X rays	4-NQO	Urethane
+×- -×-	15/76 (19 7*) 4/69 (5 8)	7/28 (25 0†) 5/103 (4.9)	4/19 (21.2) 9/113 (8.2)

Male parents were treated with X rays (504 rad), 4-NQO (10 μ g per g) or urethane (1.5 mg per g) at 8-14 days before mating. + Means that the F₁ mouse later developed lung tumour, - means that it had not developed a tumour by 8 months. There was significant difference between +×- and -×- mating at *P<0.05 and †P<0.01.

5/125 (see Table 2 legend for explanation of symbols). Combining the data, the proportion of affected progeny from $+\times-$ matings was 21.4%. The pattern of inheritance is that of a dominant with about 40% penetrance. Reduced penetrance was also found for dominant skeletal mutations⁶.

In addition, four untreated females that later developed spontaneous lung tumours produced 49 progeny. Of these, only two (4.1%) developed tumours, a value not different from the progeny of normal mice in this strain. The histological pattern was the same in the two groups. One possible explanation for the different heritability is that the spontaneous tumours were caused by somatic rather than germinal mutation. In view of the quantitative doubts about spontaneous rates, doubling dose calculations are not presented.

Although tumours were produced by both radiation and urethane, urethane failed to produce a significant increase of dominant lethals, suggesting that gross chromosomal rearrangements are not produced by urethane. To test this further, progeny of treated parents were examined for translocations detected cytologically at meiosis. Of 64 progeny from parents treated with 504 rad of X rays at post-meiotic stages, 10 had characteristic translocation configurations. Two others had small testes with no meioses, probably also caused by gross chromosomal rearrangements. One of these two had a lung tumour. Among the 54 progeny mice showing no evidence of translocations, eight had lung tumours. In contrast, no evidence of translocations was found in 50 progeny of parents treated with urethane. This difference between X rays and urethane was confirmed by genetic experiments with Drosophila melanogaster⁷. Urethane produced no chromosome rearrangements or dominant lethals, but was a potent mutagen. At the highest doses, the number of recessive X-linked lethals was equivalent to those produced by 2,000 rad of y rays.

The fact that urethane produces tumours but not translocations or dominant lethals and the observation that tumours occur no more frequently in those mice with X-ray-induced translocations (1/12) than in those without translocations (8/54) argues that the mutations producing tumours are not related to gross chromosome changes. There could, of course, be cytological changes (small deletions, for example) not detected as translocations. In any case, the tumours behave as dominant mendelian factors with a penetrance of about 40%. Reduced penetrance is not surprising in this kind of trait.

It is striking that tumour mutations occur about 10 times as frequently as dominant skeletal mutations^{4,5}. The spontaneous tumour incidence is also much higher (~5%) than skeletal mutations. It is possible that many more gene loci are involved¹²; alternatively, specific loci may be especially prone to lung tumour-causing mutations in my ICR strain.

The most important reservation regarding these experiments

is that the results may be a special property of the mouse strain used. However, other kinds of tumours (ovarian tumours and lymphocytic leukaemias), although much less frequent than lung tumours, increased in the same ratio. It is important that similar experiments should be done with other mouse strains to test the generality of the results. Confirmation of the findings in other strains would mean that heritable cancer induced by radiation and chemical mutagens becomes an important factor for study in human populations such as those of Hiroshima and Nagasaki. Note that in traditional experiments designed to test mutability in mice the progeny are not kept long enough for tumours to develop.

A host gene controlling early anaemia or polycythaemia induced by Friend erythroleukaemia virus

Tsunefumi Shibuya & Tak W. Mak

The Ontario Cancer Institute and Department of Medical Biophysics, University of Toronto, 500 Sherbourne Street, Toronto, Ontario, Canada M4X 1K9

Friend ervthroleukaemia virus (FLV) is a type-C murine retrovirus that induces a rapid multi-stage erythroleukaemia in susceptible mice¹⁻⁵. An early phase (1-3 weeks) is characterized by splenomegaly and rapid changes in erythropoiesis⁵⁻⁸, while a later stage (1-3 months) is associated with the development of clones of highly tumorigenic cells^{2-5,9}, which can be established into Friend erythroleukaemic cell lines. Two distinct isolates of FLVs, both of which can induce the early and late stages of the diseases, have been described. The original isolate (FV-A) induces a rapid severe anaemia, while a later isolate (FV-P)¹⁰, derived from stocks of FV-A, induces a rapid polycythaemia7. In addition to the contrasting changes in haematocrit, the diseases induced by FV-A and FV-P can also be distinguished. For example, while the erythropolesis in FV-A infected mice appears to remain under the control of the hormone erythropoietin^{8,11,12}, erythropoiesis in FV-P infected mice is erythropoietin-independent^{8,11-13}. Furthermore, Friend erythroleukaemic cell lines derived as a consequence of FV-A and FV-P infection also display different cellular properties^{5,9,14}. Here we demonstrate that in addition to the viral contributions, host genes play an important part in determining the nature of the disease induced by FV-A or FV-P. A new host gene which determines the induction of early anaemia or polycythaemia by FLV is described.

The polycythaemia strain of FV-P has been used extensively in studies of host genetic control as well as its interaction with the haematopoietic progenitor cells^{15,16}. Most of such studies used mice strains DBA/2 and BALB/c. We have now extended these studies to other mice strains, notably CBA. Figure 1a illustrates the change in haematocrit in DBA/2 mice following the infection by FV-A and FV-P. The data show that for FV-A, the haematocrit of the mice dropped from a normal value of 50% to ~35% by 2-3 weeks, while that of FV-P infected mice increased to over 70% during the same period. However, as also shown in Fig. 1a, following the infection of FV-P into another strain of mouse CBA, instead of increasing, the haematocrit fell to ~35%. A similar reduction of the proportion of red cells in the circulating blood was also detected following infection with FV-A. This implies that not only can a contrasting response in haematocrit values be stimulated by FV-A and FV-P, but that different haematocrit values can be induced after infection of FV-P into two different strains of mice. These rapid changes in haematocrit appear to be the effect of the replication-defective spleen focus-forming virus components, SFFV_A and SFFV_P (ref. 8) of FV-A and FV-P, respectively. The helper virus, F-MuLV, did not induce such changes in either DBA/2 or CBA mice (Fig. 1a).

It is possible that CBA mice are resistant to polycythaemia induction by FV-P and that the early anaemia observed in these mice after injection of FV-P is due to a small quantity of contaminating SFFVA in the FV-P stocks. To rule out this possibility, we have prepared a FV-P preparation by transfection of moleculary cloned polycythaemia strain of spleen focus forming virus (SFFV_P) DNA¹⁷ to NIH/3T3 cells and rescued these transfected cells with cloned F-MuLV¹⁷. Data in Fig. 1b indicate that this virus preparation, which contained only virus from molecularly cloned SFFV_P and F-MuLV, also induced an early polycythaemia (70% haematocrit) in DBA/2 and a rapid anaemia (30% haematocrit) in CBA mice. Another possibility is that inoculation of FV-P into CBA mice resulted in certain host-induced changes in the viral genomes, or that endogenous FV-A was induced, thus causing anaemia in these mice. To rule this out, a 10% spleen extract was obtained from the CBA mice 2 weeks after infection with FV-P and injected into five DBA/2 and five CBA mice. Results indicate that, similar to the original stock of FV-P, the virus in these spleen extracts induced a severe polycythaemia (average haematocrit 69± 2.5%) in DBA/2 mice and a rapid anaemia (haematocrit 40± 4%) in CBA mice 2 weeks after inoculation.

We next examined several inbred mouse strains and their changes in haematocrit after infection by FV-P. Mouse strains DBA/2, CBA, C3H, AKR and BALB/c were injected with an equal dose of FV-P and their haematocrits measured at the time of infection (0 week) and 2 weeks later. Results in Table 1 indicate that, like that of DBA/2 mice, the AKR mice and BALB/c mice strains developed rapid polycythaemia. The C3H strain, however, responded like CBA mice in developing an anaemia. These contrasting results demonstrate that host determinants have an important role in determining these early erythropoietic changes.

To examine if such contrasting effects in the changes of haematocrit as a result of infection by FV-P is the result of a single locus gene, (CBA×DBA/2) F₁ hybrid mice and mice from backcrosses of DBA/2×(CBA×DBA/2) F_1 and CBA× (CBA×DBA/2) F₁ were developed and their haematocrit changes 2 weeks after injection with FV-P were measured. The data in Fig. 2 indicate that, similar to the findings described above, all the DBA/2 mice injected with FV-P developed a rapid polycythaemia with a haematocrit value of about 65-70%, while the haematocrits of all the CBA mice dropped to 35-40%. The (CBA \times DBA/2) F_1 hybrids, however, developed a slight polycythaemia, with haematocrit values between those of CBA and DBA/2 mice, 55-60%. These data suggest that if the early anaemia or polycythaemia is controlled by a single gene, the gene has a co-dominant effect. The haematocrits of mice from $CBA \times (CBA \times DBA/2)$ F_1 appear to segregate into two groups, one group with haematocrits of 35-40% and another with values of 55-60%, while the haematocrits of the DBA/2 \times (CBA×DBA/2) F₁ mice seem to have segregated into two groups, one at 55-60% and one at 65-70%. These results indicate that the haematocrit values in the hybrid mice segregated as single genotypes, suggesting that the induction of early

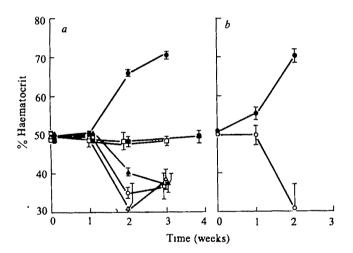

Fig. 1 a, Kinetics of changes in haematocrit values in DBA/2 and CBA mice infected with FV-P, FV-A or F-MuLV. Clonal isolates of FV-P, FV-A or F-MuLV used were described elsewhere. To examine the kinetics of changes in haematocrit values, 2×10³ focus-forming units (FFU) of FV-P, 10³ FFU of FV-A, or 2.5×10⁶ XC plaque units of F-MuLV were injected through the tail veins of female DBA/2 mice or CBA female mice (Jackson Laboratories). At weekly intervals, the haematocrit values of the mice were determined by bleeding through the tail veins of the mice with haematocrit tubes (Dade Division, American Hospital Supply, Miami). At least four mice were used for each determination. All mice were 7-10 weeks old at the time of infection. Symbols: ●, FV-P into DBA/2; O, CBA; ♠, FV-A into DBA/2 and CBA, △; ■, □ F-MuLV into DBA/2 or CBA. Bar represents 1 s.e. b, Changes of haematocrit values in DBA/2 and CBA mice after infection of viruses from molecularly cloned SFFV_p DNA and F-MuLV. Molecularly cloned polycythaemia strain of spleen focus-forming virus (SFFV_p) DNA were transfected to NIH/3T3 cells¹⁷. The transfected cells were rescued with cloned F-MuLV^{8,17}, the virus in the supernatant was injected into either DBA/2 or CBA mice and their haematocrit values were determined as described for a. Symbols: •, DBA/2; O, CBA mice. At least four mice were used in each determination. Bar represents 1 s.e.

Table 1 Early changes in haematocrit in different mouse strains following infection by FV-P

, , , , , , , , , , , , , , , , , , ,	Наета	tocrit
Mice	0 week	2 weeks
DBA/2	51.0 ± 1.0	66.5 ± 0.9
BALB/c	52.0 ± 1.5	57.3 ± 3.1
AKR	49.3 ± 0.9	71.0 ± 2.4
CBA	49.5 ± 0.5	36.8 ± 3.7
СЗН	49.8 ± 0.5	40.0 ± 1.9

2×10³ FFU of FV-P were injected into DBA/2, BALB/c, AKR, CBA or C3H mice and the haematocrit values were determined at the time of infection and 2 weeks later (see Fig. 1). All mice used were female, 7-10 weeks old at the time of infection. At least four mice were used in each determination. Error represents 1 s.d.

polycythaemia or anaemia in DBA/2 and CBA mice, respectively, is controlled by a single co-dominant locus.

The contributions of host hereditary factors in determining the susceptibility to FLV infection is well established¹⁴⁻¹⁶. Several host genes—Fv-1 (ref. 15), Fv-2 (refs 16, 18, 19), W (refs 8, 20), Steel (refs 8, 16, 21, 22) and H-2 (refs 16, 23)—are known to control the susceptibility of mice to erythroleukaemia induction by this virus. The present gene, however, seems to affect the type of erythropoietic modulations by FLV rather than the susceptibility.

This finding, taken together with the previous reports that the types of modification of the erythropoiesis patterns depend on the strain of FLV used^{8,11,12}, indicate that the modulation of the haematopoietic organization by FLV is the result of a complex array of interactions between host genes and the viral genomes. These early experiments showed that, following infection by FV-A and FV-P, certain pathological differences could 🎺 be detected. For example, FV-P induces a rapid polycythaemia associated with erythropoietin-independent poiesis^{8,11-13}, while FV-A induces a rapid anaemia associated with eporythropoietin-dependent erythropoiesis^{8,11,12}. The reason for these contrasting changes is not known. Perhaps the two viruses infect different target cells in the haematopoietic hierarchy, leading to the modulation and appearance of cells with different properties. This hypothesis is also supported by the nature of the tumorigenic colonies emerging in the late stages of the disease^{5,9}. These colonies, which are probably the result of progressions from the infected cells in the early phase of the disease, when derived from FV-P- or FV-A-infected mice, differ in their kinetics of appearance⁵, their self-renewing capacities, their incidences of chromosomal aberrations and their responsiveness to induction by erythropoietin^{9,14}

The present data indicate that in addition to the contributions of host genes in determining the susceptibility to infection by FLV, the outcome of the virus-induced erythropoietic modulations is under genetic control. We propose that this locus in DBA/2 and CBA mice, which controls the state of erythropoiesis early after infection by FV-P, be designated Fv-5. Thus, CBA mice which develop early anaemia after infection with FV-P have a genotype of $Fv-5^{aa}$ and DBA/2 mice which develop polycythaemia, Fv-5^{pp}. The mode of action of this host gene is unknown. Although it is possible that the viruses infect different target cells in CBA and DBA/2 mice, leading to the infection or transformation of non-erythroid cells or of erythroid cells with different differentiation potentials, preliminary results do not support this. Similar to DBA/2 mice infected with FV-P, the CBA spleen cells are predominantly erythroblasts. Furthermore, erythropoiesis of the FV-P-infected CBA A mice and the formation of erythroid colony-forming units were also independent of any added erythropoietin (T.S., Y. Niho and T.W.M., unpublished data). Alternatively, this gene may affect the severity of haemolysis of the FLV-transformed erythroid cells, or control the rate of proliferation and differentiation of late erythroid cells. Finally, it may function by controlling the transport of the transformed erythroid cells from the bone

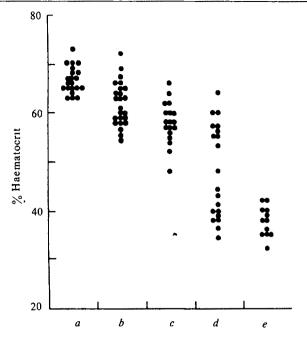

Fig. 2 Haematocrit values of: a, DBA/2; b, (CBA×DBA/2)F₁; c, (CBA×DBA/2)F₁; d, CBA×(CBA×DBA/2)F₁; e, CBA mice weeks after infection by FV-P. 2×10³ FFU of FV-P were injected into each mouse with background of DBA/2, CBA, $(CBA \times DBA/2)F_1$, $DBA/2 \times (CBA \times DBA/2)F_1$ and $CBA \times DBA/2$ (CBA×DBA/2)F₁, and their haematocrit values were determined 2 weeks after infection. (CBA×DBA/2) F_1 , DBA× $(CBA \times DBA/2)F_1$ and $CBA \times (CBA \times DBA/2)F_1$ mice were developed in the animal colony of the Ontario Cancer Institute.

marrow or spleens of these mice, thus controlling the proportion of red cells in the circulation. Comparison of the properties of the erythroid progenitor cells, the rate of erythropoiesis and the nature of tumorigenic Friend erythroleukaemic cell lines derived after infection of mice of genotypes Fv-5^{aa}, Fv-5^{ap} and Fv-5^{pp} will help to elucidate the process of leukaemic transformation by FLV and cellular heterogeneity of leukaemic clones.

This work was supported by the MRC of Canada. Note added in proof: Recent results from this laboratory suggest that Fv-5 controls the rate of proliferation of a late (post CFU-E) erythroid precursor cell(s).

Unequal crossing-over accounts for the organization of *Drosophila* virilis rDNA insertions and the integrity of flanking 28S gene

Peter M. M. Rae

Department of Biology, Yale University, New Haven, Connecticut 06511, USA

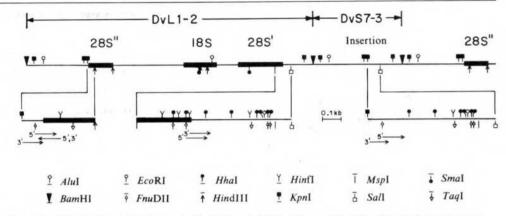

The majority of ribosomal DNA (rDNA) repeats in Drosophila melanogaster and Drosophila virilis have an insertion in the 28S rRNA coding region, and such repeats are essentially inactive in transcription1. There are two unrelated types of insertion in D. melanogaster rDNA, one of which (type 1) has some homology with insertions in D. virilis2, and is located in precisely the same position as that in the D. virilis rDNA³⁻⁶. D. melanogaster type 1 rDNA insertions fall into three size classes of 5, 1, 0.5 kilobases (kb), and sequences of shorter insertions comprise the downstream end of longer ones^{4,5} Indeed, the points at which the sequences of longer type 1 insertions depart from shorter ones are oligonucleotides that are closely related to a 14-base pair (bp) rRNA coding sequence directly repeated at the flanks of D. $virilis^3$ and some D. melanogaster4 rDNA insertions. It has been suggested that shorter D. melanogaster type 1 insertions derived from longer ones by unequal crossing-over that involved these homologies, and I show here that long D. virilis rDNA insertions may have arisen from shorter ones in the same way. Also, I suggest that such unequal crossing-over can generate intact rDNA repeats from those with insertions.

The major D. virilis rDNA insertion has been described as being ~10 kb long^{2,3,7}, although it had been noted that it appears to be a tandem duplication². Blot hybridizations using uncloned D. virilis rDNA digested with restriction enzyme combinations not previously used have now shown that 5-kb insertions are at least as frequent as 10-kb insertions, and that a HindIII cleavage site was misinterpreted in a previous study². Restriction site mapping and the sequencing of homologous regions of a 10-kb insertion verified that it is a tandem duplication. This fact, together with sequence data on the middle of a 10-kb insertion, strongly suggest that it arose from 5-kb insertions by unequal crossing-over, with the flanking 14-bp repeats of coding sequence serving as points of homology. Longer segments containing the insertion have been found from blots to have lengths that are also multiples of \sim 5 kb. If these are from rDNA, they presumably arose from unequal crossing-over between rDNA repeats having insertions of various lengths. However, they may represent non-rDNA copies of the insertion 1,2,6

The D. virilis rDNA clones pDvL1-2 and pDvS7-3 used in this study have been described elsewhere^{2,3,8}; the map of an rDNA repeat that contains a 10-kb insertion is shown in Fig. 1, together with the lengths of rDNA that were sequenced for this study.

Figure 2 (lane 2) shows the hybridization of DvS7-3, a BamHI segment of D. virilis rDNA that contains only insertion sequences (Fig. 1), to D. virilis nuclear DNA digested with SmaI+ HindIII and electrophoresed in a 0.4% agarose gel. There are no SmaI or HindIII sites in the known D. virilis rDNA insertions, but there is a SmaI site in the 28S' coding region ~2.2 kb upstream of the insertion (Fig. 1), and a HindIII site 280 bp downstream of the insertion in the 285" coding region3. The greatest amount of hybridization occurred to a band at 7.5 kb, and this length is attributable to a 5-kb insertion plus flanking coding sequences to the SmaI and HindIII sites. The next most intense band is at ~12.8 kb, and is considered to derive from rDNA repeats having 10-kb insertions. Other bands, indicated

Fig. 1 Maps of the cloned D. virilis rDNA segments DvL1-2 and DvS7-3 that together represent an rDNA repeat having a 10-kb insertion in the 28S rRNA coding region². DvL1-2 itself may be a segment derived from two adjacent repeats with 5-kb insertions, or from adjacent repeats with insertions of different size, but the contiguity in rDNA of BamHI segments comparable with DvL1-1 and DvS7-3 has been demonstrated². The distribution of restriction enzyme cleavage sites in the insertion shown indicates that it is a tandem duplication, and a

comparison of DNA sequences around the BamHI, EcoRI and SalI sites in DvL1-2 and DvS7-3 has verified this. The horizontal arrows beneath the expanded portions of the map indicate DNA that was sequenced specifically for this study. Sequencing was done according to Maxam and Gilbert¹³. DNA segments were either 5' end-labelled with $[\gamma^{-32}P]ATP$ and polynucleotide kinase¹³, 3' end-labelled with $[\alpha^{-32}P]dNTP$ and the Klenow fragment of DNA polymerase¹⁴, or 3' end-labelled with $[\alpha^{-32}P]3'dATP$ and terminal transferase¹⁵.

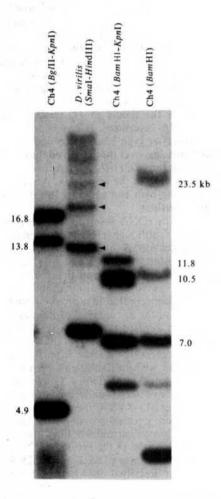

Fig. 2 Hybridization of the rDNA insertion segment DvS7-3 (Fig. 1) to a blot of *D. virilis* nuclear DNA digested with Sam → Sma and HindIII and electrophoresed in a 0.4% agarose gel. Conditions have been described elsewhere⁸. With respect to insertions in the 28S coding region, the nearest SmaI site is ~2.2 kb upstream in the 28S' portion, and the nearest HindIII site is 278 bp into the 28S" portion³. Lanes flanking the D. virilis lane contain markers of end-labelled segments of Charon 4 DNA ^{5,16}: the first lane shows a KnpI digest of Charon 4 (Ch4) end-labelled at BgIII sites; the third lane shows a KnpI digest of Charon 4 end-labelled at BamHI sites; fourth lane, BamHI segments of Charon 4. The sizes of some segments are indicated in kilobases¹⁶. Before blotting, DNA in the gel was fragmented by depurination to facilitate transfer of high-molecular weight DNA to the nitrocellulose filter¹⁷. Arrowheads indicate bands that are ~5-kb multiples of the darkest band at 7.5 kb.

by arrowheads in Fig. 2, are also 5-kb multiples of the 7.5-kb band, and the ladder may extend beyond the measurable range of segment sizes.

I determined the sequence of the very centre of a duplication to determine the precision of a tandem array. Figure 3 (centre) shows the sequence within the 0.7-kb *KpnI/SalI* segment of DvS7-3 that spans the end of one 5-kb insertion and the beginning of the next (Fig. 1). Also shown for comparison are the termini of insertions in the clone DvL1-2 (ref. 3). These are exactly represented in DvS7-3. Furthermore, they are separated in DvS7-3 by a 14-bp sequence, TGTCCCTATCTACT, that flanks insertions as a direct repeat, and is present as a single copy in an uninterrupted unit of rDNA^{3,5}.

The data indicate that tandem repeats of a 5-kb rDNA insertion arose from unequal crossing-over in which the 14-bp flanking sequence served as the point of sequence homology. An event generating a 10-kb insertion from such recombination between two repeats having 5-kb insertions is shown in Fig. 4.

The reciprocal of the product with a 10-kb insertion is an rDNA repeat having no insertion (Fig. 4), and presumably recombination between intact genes and interrupted ones can also have occurred (this is the reverse of the event shown in Fig. 4). Thus it is possible that there is a flux between populations of rDNA repeats having 28S coding-region insertions and rDNA repeats that are intact. This has a bearing on an enigmatic feature of Drosophila rDNA: while repeats with insertions are inactive in rRNA synthesis9, and the insertions themselves are probably ancient and are greatly divergent among Drosophila species2, coding-region sequences that flank insertions are largely indistinguishable from sequences in intact, functional genes^{3,5}. This is unexpected for gene copies that appear to have been nonfunctional for a very long time, particularly when insertion sequences immediately adjacent to coding regions are evidently under little or no pressure for sequence conservation^{2,5}. However, if coding regions in interrupted genes can be dissociated from insertions through unequal crossing-over involving the duplicated coding sequence at the flanks of insertions, and can exchange sequences with functional genes, then sequence integrity in the coding regions of interrupted genes would have been maintained.

There is one known case in which coding sequences adjacent to an insertion are not intact, that of the 5-kb type 1 insertion in *D. melanogaster* rDNA. There is a 23-bp deletion of coding sequence at the 28S' end of such insertions^{5,6}, and this deletion includes the 14 bp that are directly repeated at the ends of other insertions. Associated with the deletion are some other defects in the 28S' portion of the coding region⁵. One rDNA clone of three that have been examined in detail has another upstream deletion of 49 bp, and the results of blot hybridizations involving unfractionated rDNA have indicated the existence of other aberrations in the 28S' region of genes with

(285' coding region)

Fig. 3 A comparison of sequences at the ends and at the centre of a 10-kb rDNA insertion in D. virilis. The middle line is from a KpnI/SalI segment of DvS7-3 (Fig. 1) that covers the junction of tandem repeats in a 10-kb insertion. The top line shows the sequence containing the junction between the 28S' rRNA coding region and one insertion in DvL1-2, and the sequence in the bottom line covers the 28S" end of the other insertion (see Fig. 1). Single underlining indicates the termini of insertions, and double underlining represents the 14 bases of 28S rDNA that are duplicated at the flanks of D. virilis rDNA insertions. Such a direct repeat of coding sequence at the flanks of insertions relates the insertions to transposable elements³. The identity of sequences in the DvS7-3 segment with those of DvL1-2 junctions strongly suggests that the 10-kb tandem duplication resulted from unequal crossing-over involving the flanks of insertions (see Fig. 4).

5-kb insertions. The 14 bp sequence is intact at the 285" end of 5-kb insertions, and no coding region defects have been associated with the 28S" coding region⁵. There are no observed tandem repeats of the 5-kb insertion as there are in D. virilis This also reflects the absence TGTCCCTATCTACT sequence at the 28S' end of 5-kb D. melanogaster insertions, as without it, unequal crossing-over events such as that shown in Fig. 4 cannot occur.

A problem with generalization of the unequal crossing-over model arises when 1- and 0.5-kb type 1 insertions in D. melanogaster rDNA are considered. These shorter insertions are flanked by identical or similar copies of the 14-bp sequence4 yet there are no observed duplications or higher multiplications of either length of insertion (only one-half of the 1-kb insertion is homologous with the 0.5-kb insertion). There is as yet no explanation for this apparent inconsistency between interrupted rDNAs in D. melanogaster and D. virilis.

Unequal crossing-over in Drosophila rDNA has been invoked to account for differences in the degree of the bobbed phenotype between certain parental strains and their progeny¹⁰ it has also been shown to occur meiotically between sister strands at the rDNA locus in yeast11. The generation of tandem multiplications of a DNA segment containing the ampC (ampicillin resistance) gene in Escherichia coli has been suggested to involve recombination between copies of a 12-bp sequence that occurs twice within 10 kb of DNA that include ampC¹². Thus there are precedents for the model given in

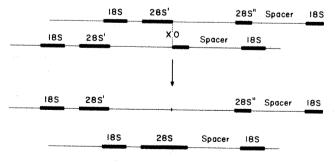

Fig. 4 Unequal crossing-over between D. virilis rDNA repeats with 5-kb insertions produces a repeat having a 10-kb insertion and one with an intact 28S rRNA coding region. The point of homology between repeats that is involved in recombination (dotted vertical line) is the 14-bp sequence directly repeated at the flanks of insertions. Crossing-over within this tetracaidecanucleotide generates a copy in the middle of the 10-kb tandem duplication, and this is indicated by a vertical dash. Sequence contexts are shown in Fig. 3.

Fig. 4. However, this is the first indication of rescue of coding sequences from an interrupted and transcriptionally inactive state to one in which the sequences can be functional in intact

Flip-flop hydrogen bonding in a partially disordered system

W. Saenger* & Ch. Betzel

Abteilung Chemie, Max-Planck-Institut für experimentelle Medizin, D-3400 Göttingen, FRG

B. Hingerty & G. M. Brown

Divisions of Biology and Chemistry, Oak Ridge National Laboratory, Oak Ridge, Tennessee 37830, USA

Cyclodextrins have proved useful as model systems for the study of hydrogen bonding¹. α -Cyclodextrin (α -CD) crystallizes from water as a hexahydrate having well defined hydrogen bonds (O-H···O) in linear and circular arrangements favouring 'endless' ... O-H... O-H... chains 1-3. The larger β -cyclodextrin (β -CD) forms a crystalline dodecahydrate, β -CD·12H2O in which X-ray localization of the hydroxyl hydrogen atoms is made difficult because 25 of the 45 hydroxyl groups are statistically disordered and water molecules enclosed within the β -CD cavity are distributed over several sites that are not fully occupied4. We have therefore carried out a neutron diffraction study of β -CD at the Oak Ridge high flux isotope reactor to determine whether there is any well defined hydrogen bonding in disordered systems. In β -CD there are 19 hydrogen bonds of the type O-H...H-O. In these bonds, oxygen atoms are in the normal O-H...O distance range⁵, but two statistically half-occupied H atoms are arranged between them. The fact that the H...H separation of ~1 A is so short that the two H atoms positions are mutually exclusive suggests an equilibrium between two states: O-H··O=O··H-O. Of the two H atoms only one is in hydrogen-bonding contact at a given time; the other one is flipped out to form a hydrogen bond with an adjacent acceptor group and vice versa. Because long hydrogenbonding chains are involved in a cooperative, concerted motion (domino effect), we have coined the term 'flip-flop hydrogen bond'. This study demonstrates that hydrogen bonds are operative in disordered systems and display dynamics even in solid state.

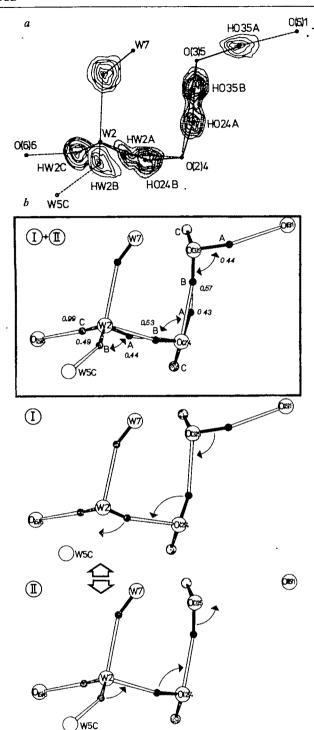

Fig. 1 a, Section of a Fourier difference map calculated from neutron diffraction data, showing D atom positions (referred to as H atoms in the text). Flip-flop hydrogen bonds Oare indicated by stippling. O, Positions of H, O and C atoms; covalent bonds; ---, hydrogen bonds. b, Same section as in a, giving an interpretation at the atomic level and showing the deconvolution of the flip-flop hydrogen bonding system into two states (I and II) having normal hydrogen bonds of the type O-H...O. Solid arrows indicate the manner in which H atoms may jump in concerted, cooperative motion from one state to another. Circles of increasing size represent H, C and O atoms, with C shown shaded and H filled. Covalent bonds are indicated by solid lines, H bonds by open lines. The water molecule, W2, displays three H atom positions, one (C) fully occupied with an occupancy factor 0.99 (1) whereas A and B are only partly filled [0.44 (1) and 0.49 (1)]. In the text, H atoms A, B and C of W2 are designated HW2A, HW2B and HW2C and those attached to hydroxyl O(2)4 are termed HO24A and HO24B. All geometrical data are close to 'standard' values and will be published in detail elsewhere.

As β -CD·12H₂O was crystallized from D₂O, replaceable hydroxyl and water H atoms were substituted by D. Here, however, we will only use the term H atom.

The hydrogen bonding scheme of β -CD was assigned from 7,378 neutron diffraction data covering a resolution of 0.56 Å. Within one asymmetric unit of space group P2₁ containing B-CD·12H₂O, there are 39 hydrogen bonds of the type O-H...O, and 19 of the type O-H...H-O in which two H atoms are located between oxygen atoms in a near-linear arrangement (Fig. 1a). In the latter, O.O separations are in the normal range (2.75-2.90 Å) as are covalent O-H distances of ~1 Å. The apparent H.··H contacts of between 0.86 and 1.18 Å, however, are much shorter than the 2.4 Å calculated from the sum of can der Waals' radii of the two H atoms6. The two H atom positions are therefore mutually exclusive and to prevent clashing, their positions are statistically only half filled and in each O-H···H-O hydrogen bond, H atom occupancies add up to ~1.0. Therefore, if one of the two H atoms is present in the O-H···H-O hydrogen bond, for geometrical reasons the other one is pushed out to form a hydrogen bond with another partner as acceptor, and vice versa. This scheme was observed in all the 19 O-H···H-O bonds. Because, on a statistical basis, the oxygen atoms in such a 'flip-flop' system are always involved in hydrogen bonding, their positions and vibrational parameters are hardly affected by changes from one hydrogen bonding direction to another. Rather, they act as 'fixed centres' around which hydrogen atoms arrange or 'flip-flop' according to optimum bonding patterns.

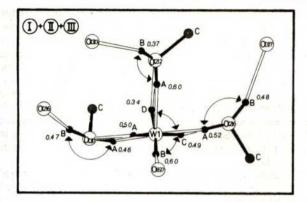

A comparable scheme has been found previously in deuterated ice^{7,8} and in ice clathrates⁹. Two deuterium atoms are located between hydrogen-bonded oxygen atoms and in ice, they are responsible for the observed residual entropy of 0.87 entropy units (ref. 10). The salient difference between ice and the system considered here, however, is that in the high-symmetry (hexagonal and cubic) space groups of ice and ice clathrate, all O and D positions are constrained by symmetry requirements, whereas they are free to arrange in β -CD·12H₂O.

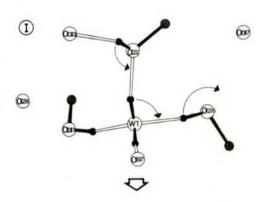

Figures 1 and 2 show examples of flip-flop hydrogen bonds. In Fig. 1, there are two flip-flop O—H···H—O hydrogen bonds connected by hydroxyl O(2)4—H, that is, W2—HW2A··· HO24B—O(2)4 and O(2)4—HO24A···HO35B—O(3)5. The H atom of O(2)4 is twofold disordered, producing HO24A and HO24B with occupation factors of 0.43 (1) and 0.53 (1). Both positions cannot be filled simultaneously. Assuming HO24A to be occupied, then the hydrogen bonding chain (I) shown in Fig. 1b is formed involving all atoms indicated by A. If, on the other hand, position HO24A is empty and HO24B occupied, then a concerted change of H atoms and hydrogen bonds occurs so that all positions indicated by B are filled (II in Fig. 1b).

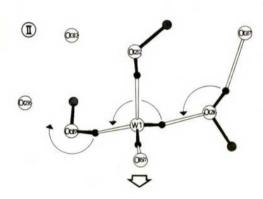

The water molecule W2 is engaged in two fully established hydrogen bonds, accepting from HW7A and donating to O(6)6, and therefore positions W2 and HW2C are fully occupied. The other hydrogen atom of W2 is part of the flip-flop system and disordered over HW2A and HW2B. All three hydrogen occupancies associated with W2 add up to 1.92 (2), in close agreement with the ideal 2.0. The two occupation factors of HW2B and HW2A, 0.44 (1) and 0.49 (1) add up to only 0.93 instead of the presumed 1.0. This is probably due to errors in measurement and refinement or is caused by incomplete H/D exchange.

In the more complicated scheme illustrated in Fig. 2, three flip-flop hydrogen bonds cluster around water molecule W1. The oxygen atom position of the latter is fully occupied, but its hydrogen atoms are statistically disordered over four tetrahedrally arranged sites with occupation factors in the range 0.34 (2)–0.60 (1), adding up to 1.93 (2). The arrangement of the water H atoms could correspond to statistical distribution over six different water orientations with unknown individual contributions.

Because the H atom positions in the flip-flop hydrogen bonds shown in Figs 1 and 2 are approximately half occupied with

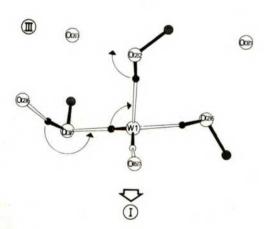

Fig. 2 A more complex system of three flip-flop hydrogen bonds connected by a water molecule, W1. The scheme observed (top) is separated into three schemes (I, II and III) having standard hydrogen bonds O-H···O; more schemes are possible because W1 is probably oriented statistically into six different positions.

occupancy factors adding up to ~1.0 in each case, the two possible hydrogen bonds O-H...O and O...H-O are energetically comparable. This means that there may be transitions from one to the other, a jump of a H atom from one position to another causing all the connected hydrogen bonds to change orientation in a cooperative, concerted mechanism, reminiscent of a relay system (domino effect; see arrows in Figs 1, 2).

The crystallographically observed atomic arrangement O-H···H-O could be due either to averaging of crystal domains or of unit cells containing hydrogen bonds O-H...O and O···H-O, or to direct observation of a dynamical equilibrium which also appears to prevail in ice9,10:

$$O-H\cdots O \neq O \therefore H-O$$

Because we do not know the residual entropy of crystalline β-CD·12H₂O, we cannot assess which of the two possibilities is more likely. In solution, however, it is certain that the dynamical system will be present. Moreover, if single 'standard' hydrogen bonds O-H...O are compared energetically with flip-flop hydrogen bonds, the latter will be preferred because of the expected advantageous entropic term resulting from statistical, near-equivalent distribution of H atoms between the oxygen atoms. In this context, it is of interest that differential scanning calorimetric measurements of β-CD·12H₂O crystals showed a strong endothermic effect at -46 °C, suggesting that below this temperature, an ordering of the whole crystal structure occurs into one or other of the flip-flop orientations11

Thus we conclude that hydrogen bonding occurs even in badly disordered systems. Note that water molecules acting as joints within a system of flip-flop hydrogen bonds click into well defined orientations dictated by optimum hydrogenbonding interactions and are by no means rotating to produce spherically averaged structures. The hydrogen bonds seem to operate in even less stringent conditions than previously assumed. This leads to flickering clusters of water occurring either in bulk or in hydration shells where disordered hydroxyl groups are dominant. If we combine flip-flop hydrogen bonds with circular structures formed by hydroxyl groups as observed in the α -cyclodextrin hydrates^{1,2,12}, an interesting dynamical system is obtained which consists of circles of four to six (or more) water hydroxyl groups with all O-H···O-H···O-H hydrogen bonds running in the same direction (homodromic, see ref. 2) and oscillating clockwise and anti-clockwise in a flip-flop manner. Such systems are favoured energetically due to the cooperative effect³ as well as to the entropic contributions of two equivalent or near-equivalent states. In water clusters, such flip-flop circles can be interconnected to form larger, rapidly interconverting and changing systems.

Conversion of the chemical energy of methylmalonyl-CoA decarboxylation into a Na⁺gradient

Wilhelm Hilpert & Peter Dimroth

Institut fur Physiologische Chemie der Technischen Universität Munchen, Biedersteiner Strasse 29, D-8000 München 40, FRG

Primary active transport systems establish electrochemical gradients of their transport substrates at the direct expense of chemical or light energy. The chemical energy can be provided by cleavage of the phosphoric anhydride bond of ATP, establishing Na+, K+, H+ or Ca2+ gradients with the respective ATPases. Whereas in eukaryotic cells the Na+ and K+ imbalance between cells and the surrounding fluids is brought about by the (Na++K+)ATPase1, no such enzyme is known for bacterial cells. Generally, the gradients of Na+ and K+ ions in these cells are believed to be generated by secondary transport systems consuming the energy provided by the electrochemical gradient of protons^{2,3}. In some bacterial species, however, sodium ions may be transported by primary ATP or light-driven sodium pumps^{4,5}. The primary sodium pump oxaloacetate decarboxylase represents a novel energy conversion mechanism in that it consumes the chemical energy of the decarboxylation of oxaloacetate to drive Na⁺ transport⁶⁻⁸. We show here that methylmalonyl-CoA decarboxylase is another example of a Na⁺ transport enzyme converting the chemical energy of a decarboxylation reaction into an ion gradient.

The action of oxaloacetate decarboxylase in catalysing the transport of Na⁺ ions across the cell membrane, thereby generating an electrochemical gradient of Na⁺ ions⁶⁻⁸, is in accord with its localization in the cell membrane and the specific requirement of Na⁺ ions for catalytic activity⁹⁻¹¹. By analogy, we hypothesized that methylmalonyl-CoA decarboxylase might also function in this way. As this enzyme apparently did not require a specific metal ion for catalytic activity, it could catalyse the transport of protons.

Methylmalonyl-CoA decarboxylase from *Micrococcus lactilyticus* (syn. *Veillonella alcalescens*) is reported to be tightly bound to the ribosomes^{12,13}, a property not compatible with a transport function for this enzyme. We have therefore reexamined the localization of the decarboxylase using chromatography of the particulate cell fraction on Sephacryl S-1000 Superfine columns. Ribosomes and membranes were clearly resolved, as indicated from the separation of the markers succinate dehydrogenase (for the membrane) and ribose (for ribosomes) and also from the change in the ratio of absorbances at 280 and 260 nm (~1 in the membrane and ~0.5 in the ribosomal fractions). The distribution of methylmalonyl-CoA decarboxylase indicated that it was attached to the membranes but not to ribosomes.

The enzyme was solubilized from the membranes with Triton X-100 and purified about 30-fold over the crude membrane extract on an avidin–Sepharose affinity column¹⁴. Examination of the cation requirement of the purified enzyme indicated that the decarboxylase was specifically activated by Na⁺ ions $(K_{\text{Mapp}} \sim 1 \text{ mM})$ at 0.10 mM (R, S)methylmalonyl-CoA). This property of the enzyme and its binding to the cell membrane are analogous to properties of oxaloacetate decarboxylase and are compatible with a function of the decarboxylase as a sodium pump.

Sodium transport was determined from the amount of radioactivity taken up into inverted vesicles of *V. alcalescens* on incubation with ²²NaCl. Whereas in the absence of methylmalonyl-CoA almost no Na⁺ was taken up by the vesicles, substrate addition resulted in the rapid accumulation of Na⁺ (\sim 1.1 nmol ²²Na⁺ per mg protein within the first 15 s; Fig. 1). Due to the high activity of the decarboxylase (0.35 U per mg protein), all methylmalonyl-CoA was decarboxylated within the 15 s, thus terminating Na⁺ uptake. The accumulated Na⁺ was not retained in the vesicles but returned to the medium at an initial rate of \sim 0.55 nmol per min per mg protein, probably due to leakiness of the membranes. These observations are completely analogous to the kinetics of Na⁺ transport into vesicles from *Klebsiella aerogenes* as catalysed by oxaloacetate decarboxylase⁷.

The action of methylmalonyl-CoA decarboxylase as a Na⁺ transport enzyme was confirmed by treating the vesicles with avidin, which simultaneously abolished Na⁺ transport and

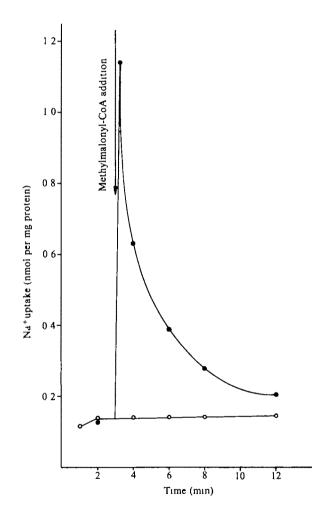

Fig. 1 Kinetics of ²²Na⁺ uptake into inverted membrane vesicles from V. alcalescens. The vesicles were prepared by passing V. alcalescens cells in 50 mM K-phosphate buffer, pH 7.5, through a French press at 8,000 p.s.i. and were subsequently isolated by centrifugation steps as described previously. The inverted vesicles (3.4 mg protein, 0.35 U per mg methylmalonyl-CoA decarboxylase) were incubated at 25 °C in a total volume of 10.67 ml 50 mM K-phosphate buffer, pH 7.5, with 0.44 mM ²²NaCl (2,800 counts per min per nmol). At the arrow, 0.3 mM (R, S)methylmalonyl-CoA (Li-Salt) was added and ²²Na⁺ uptake was determined from samples (0.1 ml) taken at appropriate incubation periods and passed over columns (0.5×2 cm) of Dowex 50, K⁺ to separate free Na⁺ from Na⁺ trapped inside the vesicles. The radioactivity of internal ²²Na⁺ was subsequently determined by liquid scintillation counting (•). O, Control without methylmalonyl-CoA addition.

Table 1 Avidin-induced inhibition of methylmalonyl-CoA decarboxylase-catalysed Na+ uptake into inverted vesicles

decarboxylase activity (Table 1). A parallel incubation with an avidin-biotin complex, however, did not affect either of these activities, ruling out the possibility that the avidin might act on the transport system in any way other than by a complexing of the biotin prosthetic group of the decarboxylase. The products of the decarboxylation, propionyl-CoA and bicarbonate, were unable to substitute for methylmalonyl-CoA in inducing Na+ accumulation to any considerable extent, thus confirming that Na+ is transported during the decarboxylation reaction. The function of methylmalonyl-CoA decarboxylase as a Na+ transport enzyme was further confirmed by reconstitution experiments. When the decarboxylase was purified by affinity chromatography on avidin-Sepharose and incorporated into phospholipid vesicles by the detergent dilution method¹⁵, using octylglucoside as the detergent, the reconstituted proteoliposomes were able to concentrate Na+ ions about six times over the incubation medium in response to the decarboxylation of methylmalonyl-CoA.

The mechanism of the Na+ transport was investigated by analysing the effect of certain ionophores. If the Na+ transport was electrogenic, creating a membrane potential, this could be limiting for the amount of Na+ accumulation, as has been shown to be the case for oxaloacetate decarboxylase. The membrane potential would be discharged in the presence of valinomycin and K⁺ by the electrophoretic movement of K⁺ ions. In these conditions, about twice as much Na+ was accumulated in the vesicles as in the valinomycin-free controls (Table 2), thereby indicating the presence of electrogenic Na+ transport. The uncoupler carbonylcyanide-p-trifluoromethoxy phenylhydrazone also increased Na+ uptake within the vesicles, although less efficiently. This effect is probably also due to discharging of the membrane potential. Furthermore, the result indicates that the generation of a proton gradient is not the primary event for the Na+ transport. As expected, the accumulation of Na⁺ inside the vesicles was completely abolished by the presence of the Na⁺ ionophore nigericin.

Thus, our results characterize methylmalonyl-CoA decarboxylase as a new transport enzyme for Na⁺ ions. The enzyme

is closely related to the Na⁺ pump oxaloacetate decarboxylase⁶⁻⁸ and both enzymes constitute a new group of vectorial catalysts, converting the energy liberated by decarboxylation reactions into ion gradients. It is well known that the decarboxylation of certain 'energy-rich' carbonic acids is used as a driving force in biosynthesis, for example, in the biosynthesis of fatty acids and of phosphoenolpyruvate, where the decarboxylation of malonyl-CoA and oxaloacetate, respectively, shifts the equilibrium towards synthesis. The conversion of the energy of decarboxylation reactions into Na⁺ gradients by methylmalonyl-CoA decarboxylase and oxaloacetate decarboxylase, however, is a previously unknown biological use of decarboxylation energy, one closely related to other energy converting processes such as the formation of cation gradients by ATP hydrolysis.

MATTERS ARISING

Thermomechanical inferences from deep seismic sounding sections

CHOWDHURY AND HARGRAVES1 recently interpreted a deep seismic sounding section, between Kavali and Udipi in India, which appears to show deep faults offsetting an essentially horizontal Mohorovičić discontinuity. Reflectors below the Moho seem to have lower and more uniform apparent dips than those above it, leading these authors to suggest that "at the time of its formation [before faulting] the Moho constituted a thermomechanical boundary between rigid [folding] crust and plastic [ductilely flowing] mantle". Although elements of this interpretation are questionable (notably that folding constitutes rigid behaviour), their subsequent conclusions ignore even more fundamental considerations regarding the rheology of solids: "Ductile flow requires that the then Moho level temperatures were close to the crustal solidus [of 1,000 °C for anhydrous granulite³]. Consequently, mean geothermal gradients must have been in the range 20-30 °C km⁻¹, two or three times those inferred for present day shields4"1.

The mere fact that a rock has been plastically deformed does not uniquely determine the temperature at which that deformation took place. Steady homogeneous flow in a solid is governed by a constitutive equation relating temperature, strain rate, and stress. For à rock subjected to uniaxial compression the equation relating the shortening rate $\dot{\epsilon}$ to the differential stress σ and absolute temperature T is typically of the form

$$\dot{\varepsilon} = A \exp(-Q/RT)f(\sigma)$$
 (1)

where O is an activation energy, R is the universal gas constant and A is a constant. The form of the function f depends on the dominant deformation mechanism(s), whereas the constants A and Q are determined by the minerals present, their grain size and geometry, and the activities of any volatile phases.

Solving equation (1) for the temperature gives

$$T = Q\{R \ln \left[Af(\sigma)/\dot{\epsilon}\right]\}^{-1}$$
 (2)

from which it is evident that the temperature required for flow can be reduced either by decreasing the strain rate or by increasing the stress. The validity of this conclusion is not limited to the case of uniaxial deformation; equations (1) and (2) can be extended to more general states of deformation, although the measures of strain rate and stress must be

Table 1 Temperature limits calculated using experimental flow laws

	Minimum temperature* (°C) [Range of mean geothermal gradients (°C km ⁻¹)]	Maximum temperature† (°C) [Range of mean geothermal gradients (°C km ⁻¹)]
Quartz	175 [3-6]	710 [10–24]
Diopside	440 [6-15]	975 [14–33]
Olivine	490 [7-16]	1,040 [15–35]

^{*} $\sigma = 2.5$ kbar, $\dot{\varepsilon} = 10^{-17}$ s⁻¹ † $\sigma = 20$ bar, $\dot{\varepsilon} = 10^{-12}$ s⁻¹.

appropriately generalized and the function $f(\sigma)$ may take a different form.

To determine unambiguously the temperature at which plastic deformation ceased (and at which the Moho formed in the Chowdhury-Hargraves model) we would need to know: (1) whether the deformation was homogeneous and steady; (2) what was the appropriate constitutive relation; and (3) what were the values of $\dot{\varepsilon}$ and σ just below the Moho when it formed. Condition (1) may be

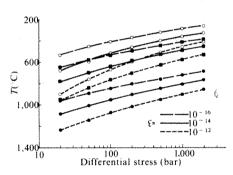

Fig. 1 Flow temperature as a function of differential stress for three strain rates. O, Quartz⁶; □, diabase⁷; ●, olivine⁵.

approximately satisfied for deep processes and geological time scales but requirements (2) and (3) cannot easily be met. If simplifying assumptions could be made about sub-Moho mineralogy and deformation mechanisms, an empirical flow law⁵⁻⁹ might be used. Similarly it could be assumed that currently estimated deep crustal or mantle flow stresses (several tens of bars to several kilobars) 10 and strain rates $(10^{-17}-10^{-12}\,\mathrm{s}^{-1})^{11,12}$ were applicable to the process of Moho formation. Using flow laws for quartz (ref. 6 and unpublished data), diopside⁸ and olivine⁹ aggregates along with the extreme values of stress and strain rate noted above, upper and lower bounds may be placed on flow temperature from equation (2). Table 1 shows these values together with their respective mean geothermal gradients for crustal thicknesses of 30-70 km.

Evidently Chowdhury and Hargraves' model places no real constraints on crustal thermal structure; in fact their near crustal solidus Moho formation temperature and corresponding geothermal gradients are nearly maximal values in a broad spectrum of possibilities. Unique determination of thermal structure by this method requires petrological and rheological constraints which are not generally available and cannot be assumed without prejudicing the results.

I thank W. M. Bruner and P. Koch for helpful suggestions.

ROY CHOWDHURY AND HARGRAVES REPLY—Koch's argument pertains to the validity of an indirect consequence of our conclusion—the inferred geothermal gradient in Archaean times-without disputing the seismic evidence which prompted our overall speculation: that in Archaean times, the base of the crust was the base of the lithosphere 1. Nevertheless his point is well taken, because we had not considered rheology in our paper.

In essence, Koch is stating that if one takes the extreme estimates of the relevant rheological variables, one gets a wider range in the resulting geothermal gradient for our model than the 20-30 °C km⁻¹ we had inferred. These variables are (1) crustal composition and thickness, (2) stress and strain rate, (3) flow law. We do not dispute this, but would rather ask: what physical conditions are required to permit our interpretation of the seismic data in terms of the current understanding of the rheological properties of the crust and upper mantle?

It seems reasonable that the Archaean continental crust was differentiated much as it is today²—in which case anhydrous mafic granulites seem to be the likely material composing the lower crust. The "smearing out", we mentioned, would require this material to be ductile at its base. We used 38 km for the crustal thickness because it is the present average for the region under study. A 70-km thick Archaean crust seems unlikely as the Dharwar schist belts now exposed on the surface are only in the greenschist facies.

We do not believe that the possible range of values for the differential stress considered by Koch (tens to thousands of bars) is the probable range. Recent studies³ tend to suggest low stresses (10-100 bar) associated with contemporary asthenospheric flow. Similarly 10^{-14} s⁻¹ is considered to be a geologically representative strain rate4

Unfortunately rheological behaviour of geological materials in the above mentioned conditions is also not known uniquely. For example, the flow law of Goetze⁵ for olivine, reported to be valid below 2 kbar, yields a flow temperature of 1,235 °C for $\sigma = 20$ bar and $\varepsilon =$ 10⁻¹² s⁻¹ as compared with 1,040 °C from the law used by Koch. There is also the problem of extrapolating experimental values to low stresses and strain-rates.

Figure 1 shows the dependence of the flow temperature on differential stress for three compositions and three strain rates using flow laws for quartz⁶, diabase⁷ and olivine⁵. Clearly, the temperature is sensitive to chemical composition and the sensitivity increases as the differential stress decreases. Thus, if the smearing out of the base of the crust took place under relatively low stress fields (tens of bars), then the chemical composition becomes a particularly important factor in determining the actual temperature of the process. For a strain rate of $10^{-14} \, \mathrm{s}^{-1}$ we obtain a temperature range between 780 °C for diabase and 1,080 °C for olivine at 20 bar. If, as we had inferred, the structural discordance at 38 km is taken to indicate that the mantle (olivine) below was ductile and convecting, then, in the abovementioned stress and strain rate conditions, a temperature of ≥1,080 °C and a gradient ≥28 °C km⁻¹ are implied. As olivine appears stronger than other rock forming materials, this model requires that the lower crust must then have been ductile as well, and hence the base of the lithosphere must have been above the Moho-crust being defined in chemical terms without consideration of its rheological properties. If, on the other hand, the boundary marks that point in time when the descending brittle-ductile boundary in the crust reached its base. then in the same conditions, a temperature of 780 °C, and a gradient of

20 °C km⁻¹ is implied for a 'diabasic' type lower crust.

Note that the thermal gradients inferred above are entirely consistent with those claimed in our original paper, which were based on experimental evidence on the beginning of melting in silicate rocks⁸. With declining heat flow, model 1 would evolve to model 2, and in the interim, the lithosphere would include a ductile lower crust above a brittle upper mantle ("jelly sandwich") (J. Suppe, personal communication). Although model 1 may well have applied in the early Archaean, model 2 seems to be more reasonably associated with the onset of cratonic stability—which marks the end of the Archaean.

Clearly evolution of tectonic style in the Earth is associated with declining heat flow. Consideration of lithospheric evolution in rheological terms, with progressive descent of the brittle-ductile boundaries in both crust and mantle, as the Earth cooled, may help to explain the more abrupt changes.

We thank Brian Evans for discussions and computational help.

Behaviour, paternity and testes size

IN a recent issue of Nature 1,2, Martin and May, and Harcourt et al. proposed a theory that behaviour, paternity and testes size are related. This hypothesis is interesting but suffers from the use of, as a model, species in which sperm production per unit of testes, sperm per ejaculate and other important considerations can only be surmised. Perhaps larger testes size is a result of more frequent copulations or larger testes stimulate males to copulate more frequently. Are sperm numbers per ejaculate well correlated to testis size in primates? The boar, ram and bull have roughly the same testis size but daily sperm production per gramme of testis varies greatly between them, and the number of sperm per ejaculate is 10-50 times greater in the boar than in the bull or ram.

The time of mating relative to ovulation seems to be more important than any other one factor in determining paternity when two males are used at an interval in the rabbit, pig and sheep^{3,4}. When matings or inseminations of two males are coincident, then the fertility of the male and numbers of sperm determine paternity. With all these complex interactions playing an important part, it seems overly simplistic to ascribe much to testes size.

PHILIP DZIUK

 Dziuk, P. J. Reprod. Fert. 22, 277 (1970).

HARCOURT REPLIES-I agree, as stated in our paper¹, that not only are more data needed to prove fully the idea that relative testes size is related to breeding system via sperm competition but also that other factors influence the correlation, and also agree that the association between relative testes size and sperm output is largely an assumption. Nevertheless, I would argue that the correspondence between the data and predictions based on this assumption is so good that unless another hypothesis explains equally well the association between relative testes size and breeding system, ours (with its assumption) must stand as the best explanation of the correlation.

Four points can be usefully commented on in more detail. (1) Although data are lacking on, for example, sperm numbers per ejaculate, they are not totally absent, and what information there is supports the hypothesis 1,2

- (2) Dziuk writes about testes size per se; we consider relative testes size, that is, testes weight per unit body weight. The difference is extremely important, and the fact that the boar, with a greater relative testes size than the bull (and I believe the ram?), produces more sperm per ejaculate than does the bull or ram fits our theory and its assumption.
- (3) Timing of mating in relation to ovulation is of prime importance in determining paternity. However, primate males cannot judge precisely the time of ovulation. In this situation the male that inseminates the largest amounts of sperm over the longest periods will be at a competitive advantage when more than one male mates with the periovulatory female. Our argument is that to do this he requires a large volume of spermatogenic tissue and hence large testes. Dziuk implies just this

in his statement that "When matings...of two males are coincident. then...numbers of sperm determine paternity" (see, for example, ref. 3). Moreover, this statement made in relation to rabbit, pig and sheep supports our suggestion that the association between breeding system and relative testes size will be found in other mammalian orders.

(4) Finally, while the hypothesis relating breeding system to relative testes size (rather than to some more precise variable) is simple, the good agreement between the data and predictions based on the stated assumption implies that it is not simplistic.

Hexose transport in hybrids between malignant and normal cells

IT HAS been reported by White et al.1 that a decreased K_m for hexose transport correlates with malignancy in matched pairs of hybrids between malignant and normal cells. Hexose transport was measured by the uptake of 0.1-5 mM 2deoxy[3H]glucose at 20 °C; in these conditions, uptake was found to be linear for at least 10 min. No doubt the authors are aware that sugars such as 2-deoxyglucose (or D-glucose) enter cells rapidly, soon (generally within <30 s at 25 °C) establish a steady state-at intracellular concentrations which can approach that in the medium-and are, in turn, phosphorylated at slower rates which persist linearly for several minutes^{2,3}. Within 5 min of exposing Novikoff² or Lettree⁴ cells (at 25 or 37 °C) to 2-deoxy[3H]glucose at concentrations of ≤0.2 mM, for example, >85% of the radioactivity associated with the cells is in the form of 2-deoxy-[3H]glucose-6-phosphate, whereas < 15% is present as an intracellular pool of free sugar.

In other words, it is likely that the ratelimiting step is phosphorylation, not transport, of the hexose and that what White et al. are measuring is the linear accumulation of 2-deoxy[3H]glucose-6phosphate in cells. While the use of a coupled reaction' to measure a preceding one is a commonly used biochemical technique, its validation does depend on confirmation that the second reaction is not rate-limiting. The article by White et

Table 1 Kinetic parameters of 3-O-methyl-Dglucose uptake in malignant and non-malignant cells

Cell type	Vmax	K _m
CBAT ₆ T ₆	325.1 ± 26.8	4.419 ± 0.520
fibroblasts	420.3 ± 90.8	4.868 ± 1.214
PG19	106.6 ± 5.1	2.114 ± 0.172
	116.6 ± 18.2	2.211 ± 0.460
1Acn2	331.2 ± 40.2	8.495 ± 1.282
1Acn1TG	107.6 ± 7.3	2.771 ± 0.241

The uptake of 3-O-methyl-D-glucose measured by the technique previously described1 for 2-deoxyglucose with the following modifications: (1) 3-O-methyl-D[1-3H]glucose (0.1-5.0 mM; 10-500 mCi mmol-1) was added to the cells in a volume of 250 µl and its uptake terminated by washing the cells twice with 1 ml of ice-cold phosphate-buffered saline.
(2) At 20 °C, uptake of 3-O-methylglucose is linear for only 1-2 min, so that correspondingly shorter incubation times were necessary. Kinetic constants were calculated as before from the linear portions of the uptake plots.

al,1, however, contains no mention of the phosphorylation reaction, let alone measurement of intracellular 2-deoxy[3H]glucose and 2-deoxy[3H]glucose-6-phosphate. Moreover, some authors have suggested that it is sugar kinases (not sugar transport per se) that are different in transformed and normal cells⁵

Although the results of White et al.1 clearly show that malignant cells take up hexoses at low concentrations better than their non-malignant homologues, the claim of these authors that their "findings leave little doubt that malignancy is closely linked to a decrease in the $K_{\rm m}$ of the membrane hexose transport system" seems as yet unjustified.

WHITE ETAL. REPLY—Since our paper¹ was submitted, we have succeeded in establishing conditions in which the

uptake of 3-O-methyl-D-glucose in our cells is sufficiently linear to permit formal kinetic analysis. This has enabled us to repeat our experiments using a glucose analogue that is not phosphorylated. The $V_{\rm max}$ values for 3-O-methyl-D-glucose uptake are comparable with those for 2deoxyglucose uptake, but the K_m values are two to four times higher, indicating that 3-O-methyl-D-glucose is transported less efficiently than 2-deoxyglucose or glucose. Nonetheless, the reduction in K_m that we previously described for 2-deoxyglucose uptake also occurs with 3-Omethyl-D-glucose.

Table 1 gives representative values for CBAT₆T₆ mouse fibroblasts, PG19 malignant mouse melanoma cells, 1Acn2, a human hybrid cell line in which malignancy is suppressed and 1Acn1TG, a malignant segregant derived from this hybrid. The reduction in K_m that we described previously is thus not primarily determined by the phosphorylation reaction, but by the flux of hexose across the cell membrane. Measurements we have made of the hexokinase activity in cell homogenates indicate that there is no correlation between hexokinase activity and malignancy.

Our conclusion that malignancy is closely linked to a decrease in the K_m of the membrane hexose transport system stands.

Matters Arising

Matters Arising is meant as a vehicle for comment and discussion about papers that appear in Nature. The originator of a Matters Arising contribution should initially send his manuscript to the author of the original paper and both parties should, wherever possible, agree on what is to be submitted. Neither contribution nor reply (if one is necessary) should be longer than 500 words and the briefest of replies, to the effect that a point is taken, should be considered.

The Falklands from below

Argentina's seizure of the Falkland Islands, a test of honour for Britain that may cost it the Thatcher government, is also a test of President Reagan's peacekeeping abilities.

Falklands; one was dry, one had gas and one produced 5,000 barrels a day in test drilling. Nearer the Argentine coast, a shell well showed 3,000 barrels a day. So the theory goes, Argentina, beset by economic woes, seized the Falklands to assure supply of a new oil well.

For the most part the oil theory is rubbish. Argentina is very

What is to happen to the great white continent to the south, Antarctica, which has no voters to cast down governments or crowds to wave approving placards in the streets. It may seem trivial to talk about obscure Antarctica, currently a haven for scientists of many nations, its antique sovereignty disputes, in this solemn moment. But the Falklands fiasco has shown how rapidly the obscure far south can be suddenly important. Whether it brings war between Argentina and Britain or a stalemate and negotiations, the dispute has three serious implications for the Antarctic, a region that starts at 60 degrees south latitude, beginning south of the Falklands and South Georgia, the southernmost island taken by Argentina on its weekend spree.

First there is the extreme vulnerability of human settlements in the far south to military takeover. Most of the Antarctic stations south of South America consist of a gaggle of huts nestled against steep black mountains and glacier snouts, the men in bright coloured parkas providing the only colour in a nearly lifeless landscape — except for the thousands of screeching birds — the huts bristle with antennas, but except for a passing ship, the only communication with the outside comes by often poor radio.

The settlements in the Falklands and at Grytviken in South Georgia, different only in that they had real buildings and greener hills, were easily overwhelmed by Argentine forces coming from the mainland a few hundred miles away. It would be harder but not much for a Latin-based military force (or one based in the Falklands) to make the 800 mile crossing of the Drake passage and seize the remaining four British stations there — although such a seizure would be a willful violation of the 1957 Antarctic Treaty that demilitarizes the region, and to which both Britain and Argentina belong. It is unlikely that Argentina would risk the enormous international opprobrium that would follow such a move, but actions in the Falklands remind us how fragile are these sparse southern stations, and how valuable is the Antarctic Treaty.

Indeed, there is a real question as to whether the British Antarctic Survey, which runs the UK's science programme in the Antarctic and until now staged its far-south operations from Stanley and Grytviken, can continue to operate, although it has contingency plans (see page 593). At present, perhaps two dozen British scientists and technical personnel are either being held or are at large on South Georgia — a place whose mountainous hinterland is so impassable that one needs an axe to cut steps in the ice to cross its inland glaciers.

The second implication of the Argentine seizure is oil. According to a report presented in January by Washington energy consultant Lawrence Goldmuntz, the offshore region between Argentina and the Falkand Islands is one of four major "horizons" in the world outside the Middle East capable of producing oil on the scale of the North Sea. Recently, Exxon drilled three wells about midway between the coast and the

US contributors please note

From now on, authors in the United States and Canada should send their manuscripts either direct to London or to the Washington office, whose new address is *Nature*, 991 National Press Building, Washington, DC 20045; manuscripts should no longer be sent to *Nature*'s New York office.

nearly self-sufficient in oil, and by inflaming a dispute to ownership of the Falklands, it would certainly not encourage major oil companies to take out leases. Despite having one of the widest, potentially richest continental shelves in the world, big oil companies have not exactly flocked to do business with Argentina. While its own near-shore shelf and Tierra Del Fuego remain undeveloped, it is hard to justify a push in the unexplored far-off Falklands. Yet the dream of oil wealth may have played a subliminal role in the seizure of the Falklands, and will play a key role in the disposition of Antarctica. Just to the south in the Weddell Sea (claimed by Argentina, Britain and Chile) sedimentary rocks are many kilometres deep while the shelf itself is larger than all of Venezuela. Argentina, West Germany, Norway and even the Soviets have been surveying the geology of the region, to get basic geological data as well as some idea of its oil potential.

The Falklands experience shows that arcane notions of national sovereignty, when combined with the dream of great oil potential, can be an explosive combination. It is easy to laugh at the obscure theories under which seven nations, and potentially several others, claim national sovereignty in Antarctica. It is also easy to dismiss the Antarctic's oil potential as purely hypothetical, as no serious exploration has been done. But the Falklands experience also shows that, nonetheless, the potential for international mischief is great.

The third and most important implication of the Argentine seizure of the Falklands is that it strains international relations at the far south at a delicate moment in Antarctic diplomacy. Argentina itself convened last year the first major international discussion by the 14 Antarctic Treaty powers of how they should dispose of Antarctic minerals — a subject not covered by the original treaty. A second meeting will be held in New Zealand in June, and the list of full parties to the treaty includes many of the key players in the Falkland Islands dispute. After the Buenos Aires meeting, the group showed some promise of being able peacefully to resolve this contentious issue — going as it does, to the heart of the sovereignty dispute. But if Britain and Argentina must use the New Zealand meeting to pound shoes on the table over the Falklands, the result could be disaster for Antarctica.

Clearly, the boundary of the Antarctic Treaty area at 60 degrees south latitude, which in reality is only a windy, stormy sea, should be treated as an iron wall diplomatically by Argentina, Britain and the other Antarctic Treaty nations. Every effort must be made to keep the dispute — no matter where it stands then — from spilling over into the Antarctic question. This will be difficult indeed, but the parties would do well to remember that the Falkland Islands are only 6,200 square miles, about the size of Connecticut or Wales. The Antarctic area, besides comprising an entire continent, one fifth of the world's ocean water by volume, and its largest potential fishery, contains one fifteenth of the Earth's surface. It would be a shame if a dispute over these tiny islands, however serious, were to spoil it.

Graduate students galore

The government document on British graduate education fails to grasp conspicuous nettles.

The poor, it is said, are always with us. So too are graduate students, called postgraduate students in the United Kingdom. And the analogy with the poor is not misplaced. One of the strongest threads running through the report of the working party on postgraduate education in Britain set up by the Advisory Board for the Research Councils in 1979 and published last week is the evidence it provides for the impoverishment of graduate students while following their courses and the poor financial prospects which await them afterwards. This is one reason why any thorough study of the arrangements for organizing and supporting postgraduate students must also ask whether the whole enterprise is worthwhile. This study*, which bears the unmistakable stamp of its chairman Sir Peter Swinnerton-Dyer, has done this and more. While concluding that graduate students (a comparatively recent innovation in British universities) have come to stay, the working party has also provided a view of the working of the British system of higher education that could not otherwise have been obtained.

Part of the trouble with graduate education is that it does not fit in easily with the rules that the administrators of higher education have developed for deciding how much money should be spent on supporting universities. So much is evident from the length of time taken after first graduation for different students to qualify for a PhD or some equivalent research degree. Why should some students take only two years, and others five or more? What, in any case, is signified by a PhD degree? Does it denote competence in research, or extra knowledge in some special field or is it merely a sign that its usually proud possessor has qualified by earlier performance for financial support or has been sought after as a research assistant by some supervisor looking for help with his own research? Because circumstances may make each of these readings valid, it is natural that administrators should be at a loss to know how much public support should be devoted to graduate education. These are some of the perplexing questions that seem to have prompted this working-party's study.

So far as they go, the recommendations of the working party are sensible enough. Yes indeed, it says, the time has come for the British government to give up the attempt that its predecessors have made ever since the Second World War to justify spending on university research by means of some calculation that there is a direct link between research expenditure and the improvement of national prosperity. Moreover, the argument goes, it is also impossible, or at least impracticable, to relate public expenditure on the support of graduate students to the needs of employers in different fields. For what employers consider to be their needs are moving targets. The only substantial exception to this chastening truth, the report concludes, is that there may be a continuing need for short-term graduate courses in fields such as computer science or toxicology, where shortages of skilled manpower have recently become apparent — and where they may nevertheless disappear without reason any time. So, the argument goes, the research councils should be quicker off the mark both in their willingness to support courses such as these, if necessary at universities chosen centrally — and then more ready than they are at present to close them down. Nobody will dissent from these conclusions. How readily will the research councils adopt them?

In at least one important respect, however, it is unfortunate that the working party has not gone further. As things are, the chief source of support for graduate students at British universities are the research studentships handed out each year by the research councils. The chief recipients of these grants are not, however, students but the departments which eventually house them and which are, within the rules, then empowered to select the students they consider to be best qualified for a career in research. The working party recommends that the research councils should be more vigilant than in the past in matching the

quotas to the reputations of their dependent departments research — and that departments whose students seem to take to long to qualify for their degrees should be penalized. The snag that in present circumstances, the principle of the quota syste needs radical re-examination. When the whole pattern of Briti higher education is being changed in such a way that sor university departments will become centres of excellence at others in the same field will have virtually to abandon hope of evbeing strong in research, is it equitable or even wise that the appointment of state-subsidized graduate students should be be entirely to the lucky (and no doubt deserving) university departments? Should there not at least be some device for making sure that promising people from less favoured universities have chance?

The working party might also have profitably gone further in i examination of the character and quality of graduate education British universities. It seems to have been mesmerized by the publicity given in recent years to the sharp difference between th tenor of PhD courses in the natural and the social sciences. In th natural sciences, it seems to be accepted that in three years c thereabouts, a person can pick up a sense of how to conduct research and also to carry out a substantial piece of work, but the in the social sciences it takes three years to acquire "researc training". So, the working party argues, the social science departments of the United Kingdom should tailor their graduat courses to the acquisition of research skills; whether or no successful students are then given a PhD degree become irrelevant. But how does it arise that in the United States an elsewhere, the normal pattern of graduate courses in the natura sciences includes a more substantial element of research trainin ("taught courses" and all that) and often a longer time i harness? Has the committee plumped for three years as th normal period of graduate education leading to a PhD out of deference to the British Government's wish to economize where i can, and without sufficient regard for the quality of graduat education?

The economic value to students of graduate education in British circumstances is exceedingly problematical. Starting salaries for PhD graduates tend to be lower than those of people who find jobs immediately after their first degree, no doub because substantial proportions of PhD graduates choose to take jobs in academic life. The working party's survey of employmen among British graduates of various kinds does not pretend to throw light on economic prospects in the longer term, which is entirely forgivable. But the data that it has uncovered are sufficient to give the lie to the now common supposition in Britair that graduate education is an extravagant luxury, a way in which perpetual students may forsend the harsh realities of the rea world for a few years — and often at the public expense. So the working party is right to flirt with the notion that the public stipends of chosen graduate students should be linked not with the grants paid to publicly-supported undergraduates but with those of research assistants doing real jobs in a laboratory environment.

Fine tuning such as this will help to make the present system function more efficiently, but will not by itself revivify graduate education in British universities. Traditionally, PhD courses have been devices for selecting future academics but, when universities are shedding staff, there are many fewer opportunities than aspirants. Is it then surprising that many graduate students become dispirited, and give up along the way? So the most urgent need is that universities should acknowledge that even the most talented graduate students will need to find other than academic jobs. Industrially related graduate courses, such as those sponsored by the Science and Engineering Research Council are valuable but will not suit every need. So should not universities pay more attention to the fate (as well as the selection) of their graduate students? And should not more of them acknowledge that there is a crying need for more than one-year graduate courses designed deliberately to round off the standard three-year first degree course by the acquisition of some employable skill?

*Report of the Working Party on Postgraduate Education, Cmnd. 8537, HMSO, £7.00.

Antarctic research hit by crisis

BAS counts the cost of island invasion

The present dispute between the United Kingdom and Argentina over the Falkland Islands has raised fears about the future of the British Antarctic Survey. But according to the survey's director, Dr Dick Laws, the invasion of the islands by Argentina came too late to have much effect on this season's work, with bases on the Antarctic continent already preparing for the long isolation imposed by the austral winter.

The British Antarctic Survey depends on the Falkland Islands to maintain contact with its research stations. The US National Science Foundation has agreed to provide a temporary commercial relay service via its base on the Antarctic peninsula, Palmer, stressing that it would only pass on messages of a scientific nature and would not handle those dealing with "political matters". In the long term, though, the communications problem could be resolved by setting up a new relay station, probably at the existing British base on Signy Island, in the South Orkneys. The Falklands are also used by the survey as a supply base, and although not indispensable, loss of those facilities would undoubtedly add to the difficulty and cost of operations. Alternative refuelling facilities within easy reach of the British bases are in the Magellan Straits, but so far Chile has not offered use of these.

Direct confrontation between the survey and the Argentinians has so far only occurred on South Georgia, where the commander of Grytviken base is also the senior representative of the Falkland Islands government. Grytviken, base for 26 of the survey's scientists at the time, had earlier been the scene of fighting between Royal Marines and Argentinian forces, although it is not yet known whether the base suffered any damage. Operations at Grytviken were in any case due to be reduced as from this month following budget cuts, despite pressure to maintain a British presence there. South Georgia has recently become a centre for work on krill, whose study as the dominant planktonic organism in the Southern Ocean is important for the exploitation of the Antarctic seas.

These problems come at the end of a troubled season for the British Antarctic Survey. In November the survey lost its two aircraft in hurricane-force winds at Rothera Station, resulting in the cancellation of virtually all Earth science projects, which rely heavily on air support of field parties. Damage to a De Havilland Twin Otter aircraft and the research vessel

South Georgia, showing the British Antarctic Survey's base at Grytviken (left) and the former whaling station (foreground).

John Biscoe the previous year had already meant abandoning that season's marine biological work, and cutting short other research programmes.

However, the future for what is widely acknowledged to be one of the most costeffective research organizations operating in the Antarctic, is not entirely bleak. The Natural Environment Research Council, who provide the survey's annual funds of £5.6 million, have provided an additional £1.8 million for the purchase of two new aircraft, and £1.3 million for the rebuilding of an important station at Halley Bay, now nearly ten years old. Collaborative research with West Germany is another route that the survey has been exploring to keep within its budget.

The Argentinian action will probably not immediately affect the activities of other nations in the area, which include the United States, the Soviet Union, Poland, Chile and Argentina itself, as none of these rely upon the Falklands for their communications or supplies. Although Argentina's own research efforts have been extremely limited, it is at present collaborating with the French in glaciological work, and plans exist to site a ground station for the first European Space Agency remote sensing satellite to be put into polar orbit, at the Argentinian base of Marambio.

Clearly the Falklands invasion is going to affect Argentina's standing amongst the Antarctic Treaty nations, due to meet in Hobart in two months' time to discuss the future exploitation of a region with a hitherto exemplary history of peace and international cooperation. David Millar

Graduate students on shorter lease

British postgraduates take too long to complete their PhD theses, according to the report of a working party on postgraduate education published last week. Blame is laid primarily on the universities, although the research councils are also criticized for not taking matters more firmly in hand.

The working party, set up in 1979 by the Advisory Board for the Research Councils, found wide discrepancies in PhD submission rates between universities and between the natural and social sciences. Its recommendation that the research councils award postgraduate quotas on the basis of a department's past completion record is being taken up by the Science and Engin-

eering Research Council (SERC) in deciding quotas for 1982-83. SERC has also published a pecking order of universities based on PhD completion success which is intended to shame universities into remedial action.

The working party was set up two years ago under the chairmanship of Sir Peter Swinnerton-Dyer, then vice-chancellor of the University of Cambridge, to advise on postgraduate education policy. It has managed to comply with its remit to assess the ways in which research councils make awards to universities and particular disciplines and whether sufficient postgraduates of the right quality are produced. But the task of determining

whether postgraduate education is meeting manpower needs proved too complicated, chiefly because postgraduates often find employment in areas outside their disciplines of study and employers are usually unable to indicate precisely their future needs at postgraduate level.

The working party report concludes that postgraduate education should continue much at the present level, but suggests that the Natural Environment and Social Science Research Councils should take a leaf out of SERC's book by encouraging specific postgraduate advanced courses in subjects for which there is a growing need.

PhD success rates of SERC-supported students by subject

	100
Subject	Success rate (%)
Biology	68
Chemistry	75
Physics	61
Maths	56
Astronomy	58
Engineering	52
Social science	39
Average	58.4

The data are for 1974 and 1975 starts, and were collected in July 1980-February 1981.

Strangely enough, however, unemployment rates are greater for those who have followed advanced courses than for those who have completed research studentships and, in the same breath, the working party also recommends that SERC should move towards research rather than advanced course studentships. It points to the reluctance to wind down courses once a specific manpower need has been met and SERC's difficulty in finding students of sufficiently high calibre to fill the places reserved for advanced engineering courses.

The universities come in for the worst drubbing. Poor PhD completion rates are attributed mainly to the morale of particular departments and the lack of adequate supervision. Poor supervision, the report says, can lead students to an unwise choice of research topics and can result in inadequate training in the techniques of research.

On the substantial differences in PhD completion rate between the natural and social sciences, the report says that there are inherent differences between the subjects. Thus social science students concerned that their first work should be a magnum opus, have a greater tendency to take on research topics which are far too ambitious to be completed within the normal three years. Perhaps, therefore, it is no surprise that 54 per cent of those embarking on PhDs in the natural sciences in 1975 had completed within five years compared with only 31 per cent in the social sciences.

Nevertheless, the working party finds the PhD completion rates in both disciplines "wholly unsatisfactory". The criteria for a PhD may have become more stringent in recent years, says the report, leading some students to take up topics unsuitable for a three-year study. Another

Average salary of graduates by occupation and highest postgraduate qualification achieved (1979-80)

Engineering and technolog. None	
	£5,520
MA	£5,700
PhD	£5,085
Science	
None	£5,350
MA	£5,970
PhD	£4,855
Social studies	
None	£5,810
MA	£5,970
PhD *	£5,000

problem is that students from small departments can lose motivation, especially if inadequately supervised. It therefore recommends that the research councils concentrate their postgraduate awards in larger departments where students may be attached to groups of experienced researchers working on a particular problem, and that supervisors should take more care to fulfil their responsibilities. The aim should be to complete research work within three years and to submit a final thesis before the end of the fourth.

The working party's report recommends several remedial actions. Universities should monitor research students at the end of their first year of postgraduate study and relegate those unsuited for research to MSc courses. Both outside academic institutions and industry should have a greater role in the choice of an individual's research topic. Finally, the research councils should review their postgraduate policies every four years, taking into account representations from potential postgraduate employers. Judy Redfearn

University research staff

Postdocs' plight

More than a quarter of the academic staff at the University of Bristol are contract researchers — postdoctoral students who in years gone by would now be on the academic staff. This is one of the more startling conclusions of a detailed survey of Bristol academics just completed by the lecturers' trade union the Association of University Teachers (AUT).

AUT claims that this is the most comprehensive study of university employment yet undertaken in Britain, and it reveals the frightening extent to which universities appear to be relying on labour which, if the research councils firmly apply their rules of cutting off postdoctoral support after, say, six years, could rapidly be lost. Nearly two-thirds of the contract researchers have less than a year of their present contract to run, the survey showed. Thus the university system could shrink without the government lifting a finger.

Naturally, AUT is most concerned about the individuals who may lose their jobs. A third are over 30 years old, one in five has dependent children, and nearly 40 per cent of researchers who have either masters or PhD degrees have no "academic status" (granting them voting and library rights, for example) in the university.

The survey, says AUT, "shatters the myth" that contract research can be regarded as a brief step on the way to an academic post. Nine per cent of the researchers surveyed had had four or more contracts, and 34 per cent, two or three. Twenty-eight per cent of the contract researchers had already been in research

Med comes clean

Political bickering between the 18 countries surrounding Mediterranean has not stopped the initialling of the fourth protocol and arm of the United Nations Environment Programme's (UNEP) plan to save the Mediterranean from further environmental damage. Mediterranean action plan was launched at the Barcelona convention in 1976, and the latest agreement obliges the signatory countries to set up coastal protected zones. The aim is not just to preserve a representative cross-section of Mediterranean ecosystems but also to foster commercially viable farms for oysters, lobsters and other shell fish.

The 1982-84 budget of \$7 million will mostly be shouldered by Italy, France and Spain, with \$400,000 from the EEC itself. A major spur for this spending is the concern that environmental dangers will affect the tourist trade. From a scientific point of view the protected areas will be useful for baseline studies of ecosystems to see whether coastal waters are getting worse or better.

Among the Mediterranean species in danger of extinction are the monk seal, marine turtle, European otter, Dalmatian pelican, peregrine falcon, oysters, mussels, the Iberian midwife

toad, the pied kingfisher and the spectacled salamander. UNEP hopes that the present number of 15 marine parks and reserves will eventually grow to at least 100.

Jasper Becker

In a report on the survey addressed to the university administration, AUT makes thirteen recommendations, most of which entail effectively putting contract workers on the staff.

According to AUT, the contract researchers should be given academic status, salary scales and a career structure. The university should have a contingency fund to support contract researchers between contracts, and it should "exert pressure" on the research councils to develop "a more positive approach" to the employment conditions associated with their contracts (which support 60 per cent of the researchers concerned). AUT also recommended that the universities should abolish waivers in contracts, which absolve them from paying redundancy pay and remove the right of appeal against unfair dismissal.

• In a survey of the employment prospects for postgraduate astronomers in Britain, the Royal Astronomical Society (RAS) has come to conclusions which broadly confirm the AUT study at Bristol (see above). Some 42 per cent of respondents were in the fourth or later year of a postdoctoral appointment. And 40 per cent of non-tenured astronomers are over the age of 30. RAS respondents were also asked if their degrees and research enhanced their employment prospects. The proportion saying yes fell with increasing qualification, from 79 per cent for the first degree to only 56 per cent for postdoctoral Robert Walgate research.

British Aerospace

Looking good

A new mood of optimism prevails at the space and communications division of British Aerospace. Not surprisingly, the company is delighted at last month's news that the Hughes Aircraft company is to build up to 16 Intelsat-VI telecommunications satellites: as principal subcontractor British Aerospace stands to win orders worth up to £50 million over the next seven years. And having also won the contract to build the European Space Agency's next generation telecommunications satellite, L-sat, the company is now said to be working to capacity.

The arrangement with Hughes over Intelsat VI, however, is just one step towards what is hoped will develop into wider cooperation. British Aerospace, through its participation in the programmes of the European Space Agency, believes that its credibility is now well established in Europe but that it will never enter the US market alone. Thus the link with Hughes is cherished.

The Intelsat VI contract could be worth \$1,600 million to Hughes if options on all 16 spacecraft are taken. The plan is to build five spacecraft initially for launch aboard Ariane or the space shuttle from 1986 onwards. Hughes has taken many of the prizes in the Intelsat developments — only

contracts for Intelsat III and V were awarded to other companies, TRW and Ford Aerospace.

The capital for the Intelsat VI development will be raised by the 106 member organizations which consist mainly of national telecommunications services. The largest shareholders are the United States, with 20 per cent of the shares, and British Telecom which holds a 13 per cent share. Intelsat VI will carry 33,000 voice and four television channels, more than twice the capacity of Intelsat V. The design, which incorporates a satellite-switched time division multiple access capability for digital transmission, may be up-graded to 100,000 voice channels later.

UK cancer research

Marking time

Britain's leading cancer research laboratory, the charitably supported Imperial Cancer Research Fund (ICRF), claims it is running short of cash — despite last year's income being the largest ever. New fund-raising mechanisms are being sought, including high-street shops and — in the long term — biotechnology.

Where has all the money gone? ICRF was criticized a few years ago for being overcautious, salting away charitable pennies in an endowment fund while spending too little on current research (only 32 per cent of its income in 1971). Now ICRF claims the balance has gone too far the other way: 58 per cent (£10 million out of £17 million raised) was spent on research in 1981, and savings have fallen correspondingly from 44 per cent in 1981 to 20 per cent last year. This year there is talk at ICRF of cuts: perhaps a loss of six staff, whereas over the past three years staffing levels have risen by 50 per cent.

The recent expansion has been the work of Dr Walter Bodmer, present research director, and his deputy Dr Michael Crumpton, but the spending seems to have overshot the mark. Government spending cuts are blamed. Not that the government supports ICRF, but cuts in the Health Service and in universities have meant that research councils, and bodies such as ICRF, have found themselves spending more than expected to provide basic services when they collaborate with hospital clinics or university laboratories.

ICRF commitments to support a new cyclotron for neutron therapy at Clatterbridge Hospital near Liverpool (the ICRF contribution is £3 million), and the building of a new £12-million laboratory site at South Mimms in north London, to replace the Mill Hill site (whose lease runs out in a few years' time), have also eaten into the budget.

The remedy will be to halt the expansion of the research budget and to attempt to raise more money by appeal — difficult in the present economic climate — and by

other means. One plan is to open shops selling second-hand clothes and bric-a-brac along the lines of the operation run by Oxfam, the famine relief organization.

ICRF is also making its entry into biotechnology. The prime objective is not to make money, says Dr Bodmer, although money would clearly be welcome if it came along. Rather, the principle will be to make commercial agreements which will speed the distribution of clinically or experimentally useful products (such as monoclonal antibodies) but to avoid "inappropriate" exploitation of the products outside ICRF control. The fund has engaged patent and commercial agents to help in this activity.

To speed this work, the South Mimms site (which should have opened in 1986) will have what is described as a "pilot plant" for large-scale cultures, which will have the double function of supplying the ICRF laboratories with materials and of testing cultures for potential industrial scale-up.

In the rest of its space, South Mimms will house the research services presently at Mill Hill and at the main ICRF laboratory in Lincoln's Inn Fields. After all the shuffling, space would be left at Lincoln's Inn Fields in 1985–86 for perhaps two new groups. Oncogenes and growth factors are among the research areas that are under consideration.

Robert Walgate

Biotechnology

Endorphin now

University College London last week announced a new joint venture in biotechnology that is more significant as a sign of the times than for the sum of money involved. Nevertheless, for Professor Brian Rabin and Dr Peter Butterworth of the college's biochemistry department, the \$240,000 contract to clone pancreatic endorphin is a godsend when the British government's economies in higher education are beginning to bite.

The contract with University College comes from Endorphin Inc., a company founded in Seattle in February. The company is equipped with venture capital, a patent and a president, Professor John Houck, who uses the money he has raised to support his own laboratories at the Virginia Mason Research Center in Seattle and now to support the University College project.

Professor Houck founded the company on the basis of his discovery that pancreatic tissue contains a hormone of potential therapeutic value. The hormone, not yet completely characterized, is related to the endorphins which also have therapeutic potential, particularly as analgesics. According to Professor Houck, however, whereas intravenously administered endorphins cannot readily reach the brain in an active form, the pancreatic endorphin can do so.

To prove the point and to prepare the way for clinical trials, Endorphin Inc. now needs a quantity of pancreatic endorphin that would be difficult to purify from pig pancreas but should be well within the production capacity of bacteria into which the relevant gene has been cloned.

The choice of University College for this task seems in large part to have been based on the fact that Professor Houck has been a visiting fellow there for several years. It may also have been cheaper to contract for the work in the United Kingdom than in the United States. But for the department of biochemistry, whose annual support from the university for overheads has been cut from £80,000 to £60,000 (an even more drastic cut in real terms), the contract allows at least one project to be carried out

in style.

Dr Butterworth claims that the normal funds available to university departments are now simply insufficient to buy the radioisotopes and restriction enzymes necessary for most gene cloning projects. Nor is there a wealth of British venture capital waiting to help out. Since matters are likely to get worse rather than better he and Professor Rabin hope that the contract from Endorphin Inc. will be followed by others

They hope also that the gene cloning for Endorphin Inc. is successful enough for the contract to be renewed in two years' time and that pancreatic endorphin eventually reaches the market. If it does University College stands to gain a one per cent royalty on all sales.

Peter Newmark

Europe leads on sequences

Europe appears, for a change, to have beaten the United States to the mark. The European Molecular Biology Laboratory (EMBL) at Heidelberg has announced the formation of a nucleotide sequence library, while the National Institutes of Health (NIH) in Washington are still deliberating the question.

Not that there is any sense of competition. Greg Hamm, manager of the Heidelberg library, is "still talking" to NIH, and wishes to cooperate with any system that NIH may set up. But EMBL was under pressure from European scientists to start now, before sequence data were irretrievably lost. EMBL is not attempting to become the sole manager of world sequence data, Hamm insists.

The question now is how to collect the data efficiently. The 600,000 nucleotides already logged at Heidelberg (they are freely available on magnetic tape) have taken an immense effort to collect. This is largely because journals do not use the clearest of systems for displaying the sequences, say Hamm and Professor Ken Murray in a letter recently sent to journal editors.

Hamm and Murray are recommending that journals should insist on the separate

submission of sequence data to the EMBL library, preferably in a format specified by EMBL, and if possible in computer-readable form. Some of these requirements, however, conflict with common format in journals. For example, codons should be presented in tens or fifteens of nucleotides rather than the triplets which correspond to the translation of the code into amino acids, says EMBL, to reduce counting errors; and the marking of reading frames and alignment of comparable sequences should be avoided.

According to Hamm, however, such requirements are only important for the easy transferral of the data into the EMBL computer: the printed format in a journal, which is intended to present the data heuristically, emphasizing the significance of regions of a sequence, could be quite different — provided EMBL were sent the uncluttered sequence according to their own guidelines.

So far, only the Journal of Molecular Biology, edited by Sir John Kendrew, has said it will implement the EMBL proposals in full. Nucleic Acids Research is said to be "basically positive", but discussing details. Nature is considering the matter.

Polish universities

Trial by proxy

New York

The International Council for the Future of the University (ICFU), a New York based organization of some 300 academics from 21 countries, committed to the defence of Western university traditions, has launched a study of the current situation in Polish universities. This marks a major change in ICFU policy. Previous studies have dealt with Western European countries (Sweden, Italy, West Germany) to which it was possible to send working parties and in which the ICFU already possessed members who could contribute first-hand knowledge of recent events. But with no Polish members of ICFU, and with the continuation of martial law the possibility of an ICFU commission visiting Poland in the near future seems remote.

The inaugural meeting for the new study, which was held in New York earlier this month, had to do the best it could with the testimonies of visitors, including Andrzej Kaminski, a mediaeval historian who left Poland before the foundation of Solidarity, two representatives of the banned Independent Students' Union (NZS) and Wojciech Karpinski, a political scientist and former activist now at Yale. Inevitably, their accounts of Polish university history did not cover the period of martial law. The most up-to-date material, including the martial law regulations governing the universities (see Nature 31 January, p.181), came from the floor. A detailed discussion of the events which followed the military take-over was deferred to a meeting to be held in Paris later this year.

More incongruously, the reforms urged and in part initiated in Polish universities during the 16 months of "renewal" (between 30 August 1980 and 12 December 1981), had been largely directed towards greater democracy ranging from student representation on the academic councils of universities to the possible election of a Minister of Higher Education by the university rectors - a proposal put forward only a few days before the imposition of martial law, and one which was later described by Deputy Prime Minister Mieczyslaw Rakowski as "the academics running amok". This trend contrasts sharply with the attitude of ICFU, which has tended to see too much democracy as a potential threat. But this divergence of views may make it easier for the Polish authorities to accept the impartiality of the proposed ICFU study. If the Polish propagandists look at the track record of ICFU it might find it difficult to make out a plausible case that ICFU is manipulated by Solidarity extremists abroad, when for the past ten years it has systematically deplored many of the reforms since advocated by Solidarity. Vera Rich

Data banks

Right to privacy

Brussels

Following the adoption of the European Parliament's resolution on the rights of the individual with respect to data processing, it now seems that the European Commission may well start work on drafting legislation to protect the confidentiality of information held in data banks. The European Parliament's resolution at the plenary session in Strasbourg last month has particular relevance for the United Kingdom which has so far shied away from tackling the controversial issues of the freedom or protection of information.

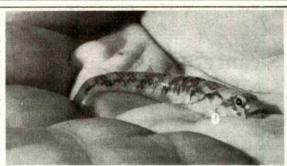

Respect for the individual's privacy has become a matter for international organizations like the EEC and the Council of Europe because of the increasing amount of information which is passed across national borders for processing or storage. The fear is that countries without satisfactory legislation on the subject might become information "havens", analogous to offshore banking centres, remote from the judicial control of the country of origin. The lack of adequate laws in the United Kingdom has become a significant impediment to the growth of the UK data processing industry, causing Sweden not to send data to the United Kingdom for processing.

At the moment there are non-binding guidelines drawn up by the Organization for Economic Development and Cooperation (OECD), and a convention for the protection of individuals with regard to automated data files has been approved but not yet ratified by the Council of Europe. The convention sets out the basic principles of data protection. These include the fair and lawful collection of data, restrictions on the storing of particular data and prohibitions on the storing of sensitive data such as political opinions. The convention also gives anybody about whom data are held the right to obtain information about the nature of the data from the agency officially responsible and to demand that inaccurate data are corrected. What categories of data can be excluded from the scope of the convention and whether dataprotection rights are given to groups of people, associations or companies are left to the discretion of the signatory countries.

The OECD guidelines, which the United Kingdom, Canada and Australia have objected to, are more in line with the views of the United States, particularly the insistence that data should flow across borders unhindered by administrative checks or delays.

Neither of these international codes is yet in operation although many European countries have well established laws on information and data control. The European Parliament's rapporteur, Hellmut Sieglerschmidt (German, Socialist), Fishy proof

This painted goby, the onehundredth species of fish to be found in the River Thames, has been greeted by Thames Water's chairman Geoffrey Edwards as proof that the Thames is the cleanest metropolitan estuary in the world. This follows the "cleanup" campaign of London's sewage system that began in 1960.

concluded that the different national rules are damaging for both the individual and for the data processing industry. In his view, the convention proposed by the Council of Europe leaves too many aspects to the discretion of signatory states. Sieglerschmidt called for a more radical EEC directive. Ideas in this proposal include: the same level of protection in both private and public sectors; the obligation for data holders to notify persons on whom information is held and permit corrections to be made; and the right of the subject of the data to claim for damages against data holders. These proposals were toned down by amendments from Conservatives. Jasper Becker

Science parks

Easy answer?

With cuts in government support hitting UK universities hard, the scramble to set up science parks is on — 15 were launched last year. Few university schemes are actually in operation, and newcomers must look to Trinity College, Cambridge, the first British academic institution to open a science park, for the blueprint.

"Science park" is a vogue term applied to many different schemes. Local authority backed projects, such as that in Warrington, aim to attract high technology industry in the hope of creating more jobs. The universities hope that science parks will earn extra income and provide an environment in which academic scientists and entrepreneurs can put new technology onto the market.

In 1973 Trinity earmarked 140 acres on the outskirts of the town for development. Phase I is now complete and the site houses 23 companies. When Napp Laboratories Ltd, a pharmaceutical company, moves into the new building it is constructing, the number of people working on the site will total 1,000. Trinity is well pleased with its park, collecting around £250,000 a year from lease arrangements, and content at having no equity shares in any of the companies. No companies have moved out and several have expanded their premises. "Every major university should have one", commented John Bradfield, bursar of Trinity.

The park's tenants range from small companies founded by one or two business-minded science graduates to

divisions of multinational companies. LKB Biochrom Ltd, the British subsidiary of a Swedish firm, was attracted to the park because of its proximity to a prestigious university. LKB moved to the park in 1974 and produces analytical instruments used in life science laboratories. According to Mr David Storey, LKB's managing director, the attitude of academic researchers to commerce has undergone "a remarkable change over the past ten years". Many members of the university now act as consultants on either an informal or formal basis, in sharp contrast with the hostility met by IBM twenty years ago when it tried to find premises in Cambridge.

Laser-Scan Laboratories Ltd, which came to the park in 1973, grew directly out of a university department. Founded in 1969 by three researchers from the Cavendish Physics Laboratory, Laser-Scan produces machines, used by the Ordnance Survey and the Ministry of Defence, based on laser scanning technology. Products made by the university engineering department's Microcircuits Group, which is supported by GEC, British Telecom and the Science and Engineering Research Council, will be marketed by a company on the park, Lintech Instruments. Although the park has demonstrated, as one research worker put it, that academics need not "wholly prostitute themselves to become entrepreneurs", it is not yet looked on as part of the university. Its distance from the university prohibits such an intimate involvement.

Cambridge Science Park is an example of a scheme established in response to government pleas in the late 1960s that industry and the universities form closer links. In 1969 a Cambridge committee chaired by Sir Nevill Mott recommended expansion of science-based industry close to the university. Dr Bradfield, who has guided the scheme from its inception, sees science parks as a means of educating academics in the commercial development of their ideas. The Cambridge Science Park has, in this respect, proved successful. But to look to science parks for a significant boost for British high technology, or as a way for universities to replace lost income, is optimistic. High technology companies are notoriously high risk ventures and present conditions are not conducive to overnight success. Jane Wynn

ORRESPONDENCE

US cancer trends

Sir - Your article on the US Surgeon General's report The Health Consequences of Smoking: Cancer 1982 (Nature 4 March, p.4) again draws attention to the importance of smoking as a cause of cancer. The 'remarkable increases in mortality from smoking-related cancers", a widely recognized phenomenon, is usefully reiterated by the Surgeon General. The concurrent decline in the death rate from all non-smoking-related cancers, also undisputed, is reported in the Nature news item. We would like to point out a misinterpretation of the reasons for the decline in cancers not related to smoking which has followed publication of the report.

The Surgeon General cites "improvements in survival rates for some cancers through earlier or better diagnosis and treatment' during the period of steeply increasing smoking-related cancer mortality rates. As had been well publicized, improvements have been made in the treatment of Hodgkin's disease, some childhood leukaemias, testicular cancer, and a few others. In contrast, however improvements in survival of people afflicted with solid tumours, those responsible for the vast majority of cancer deaths, have been small. The improvements in survival, while important, have had little effect on overall mortality from non-smoking-related cancers.

The major contributions to reduced nonrespiratory cancer mortality are the falling mortality rates for stomach and uterine cancers. These declines result not from improved survival, but from declining incidence rates for these cancers1

Stomach cancer rates are now decreasing throughout the developed world. In the United States the trend continues downwards throughout middle age, suggesting that as younger people age, they will have rates lower than those of their parents' generation. Stomach cancer mortality rates in the United States are now among the lowest in the world. Early detection and improved treatment has had little impact on the mortality rates. There has been practically no improvement in survival of stomach cancer patients since 1950.

No single explanation adequately explains the decrease in stomach cancer incidence, but several factors have been suggested as contributors: modern techniques of food preparation and storage, increased consumption of green vegetables, fruits, antioxidants (as food preservatives) and increased milk intake.

The long downward trend in cervical cancer, which began at least 40 years ago, is the chief reason for the large, steady decrease in female non-respiratory cancer death rates over the past half century. The decline began long before the "Pap test" for early detection of cancer of the cervix became widespread. The causes of this substantial improvement are not fully understood, though it appears to have accompanied general improvements in public health and living standards.

The Nature news article cites improvements in survival of prostatic, colorectal and breast cancer patients as contributing to reductions in non-smoking-related cancer mortality. In fact, mortality rates for these three cancers have remained nearly constant since 1950.

While the contemporary declines in

mortality from stomach and uterine cancers appear to be fortuitous concomitants of modern life, additional major reductions in cancer rates can be achieved with present knowledge. The evidence indicting smoking provides the greatest unrealized potential for reducing the impact of cancer

Anthrax island

Sir - We would like to deal with a number of points raised by Dr Sterne (Nature 4 February, p.362) regarding our paper on anthrax contamination on Gruinard Island1.

The main object of the 1979 survey of Gruinard Island was to determine whether or not the whole island was grossly contaminated with Bacillus anthracis. We have shown that it is not, but that the organism is found in detectable numbers in a small area.

We believe that Dr Sterne has misunderstood our view about Van Ness's assumption that B. anthracis proliferates in the soil under certain conditions². We stated in our paper that we did not believe such conditions existed on Gruinard Island. The present extent of the contamination was probably due solely to the wartime trials with some slight redistribution of the spores by wind and rain.

We agree with Dr Sterne's statement that he failed to recover B. anthracis from cadavers of cattle buried as little as three months previously because it is known that only spores survive for any length of time. The vegetative bacilli only sporulate in the presence of oxygen3,4, and veterinary officers dealing with suspected cases of anthrax do not normally open the body cavity thus ensuring that oxygen is excluded.

We have shown that if blood is added to contaminated soil from Gruinard Island the spores will germinate and proliferate. The numbers of indigenous soild bacteria did increase as a result of this procedure but the selective medium allowed us to obtain accurate counts of B. anthracis colonies. Dr Sterne rightly states that there is no experimental evidence that B. anthracis does multiply in the soil but what we have tried to show is that the possibility of proliferation in the presence of nutrients does exist and should not be entirely disregarded.

Improbable stuff

Sir - That the information content of terrestrial biology is truly prodigious¹ seems generally agreed. Hoyle and Wickramasinghe² avoid the problem of assessing repetitiveness and irrelevancy in the DNA (Nature 1 October 1981, p.333) by starting from the fact that 2,000 enzymes are common to all life. Each enzyme has a distinct "backbone" of, say, a dozen amino acids together with a specific active site which catalyses a particular biochemical reaction and is determined by, say, six further amino acids. It is presumed that these common enzymes determine a minimum information content in biological DNA.

Taking the twenty biological amino acids, one can compute the number of different combinations of Boltzmann's "permutability" P of enzyme-like chains: for 2,000 18-link chains P would be $\sim 10^{40,000}$ for 20,000 18-link chains containing the 2,000 specific ones it would be $\sim 10^{-26,000}$, while for 2,000 6-link chains it would be $\sim 10^{-13,000}$. In choosing the number of 6 to characterize the active site, Rout (Nature 18 March 1982, p.192) discounted the "backbone" but more importantly forgot that activities such as energy release from sugars or accurate DNA replication require sequences of particular enzymes catalysing reactions in a specific order.

Weighting the amino acids according to some expected abundances modifies the numbers but an index of the order of 10,000 is inescapable - that is, a probability of 1:1010,000 against finding the present enzyme system in a particular sample at a particular time as a chance arrangement. To demonstrate the immensity of such numbers, note that the product of the number of bacterium-sized drops (10⁻¹³ cm³) in the upper 1 metre of the Earth's surface water and the number of milliseconds in 4 billion years is 10 54 Alternatively, the number of UV photons over 4 eV (capable of breaking and rearranging a chain) arriving through the Earth's history is 10 49. All Earth-like planets in the Galaxy throughout its lifetime would give "only 10 ⁷⁸ or 10 ⁷³

It is probable that some simple selfreplicating systems exist that are viable in restricted environments, if only because present biology can prosper in extreme conditions and utilize a wide variety of exothermic chemical transformations 2. So life might have started from a very simple biology, arising by chance on the primitive Earth. Experimental demonstration of a practical system is not inconceivably remote 4

But why don't geocentric evolutionists (Nature 18 March 1982, p.198) face up to the awkward questions; where are all the simpler intermediate biologies - surely some should have had advantages over our unnecessarily rich biology and have left clear traces? And why should bacteria be adaptive to nonterrestrial environments and in particular be capable of space travel?

CHARLES DARWIN 1809-1882

The century since Darwin

Charles Darwin was born on 12 February 1809 and died on 19 April 1882. Here John Maynard-Smith reflects upon the 100 years since Darwin's death. A contemporary controversy is discussed in News and Views.

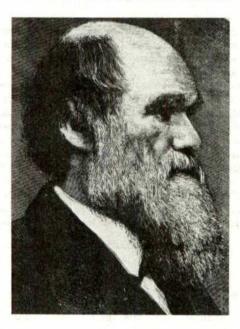

LUDWIG BOLTZMANN once wrote that the nineteenth century would be remembered as the century of Darwin. One hundred years after Darwin's death this judgement still seems perceptive. No other writer had such a profound effect on the way we see ourselves, and no other brought about so great an extension in the range of subjects which we regard as explicable by scientific theory. Here, however, I shall confine myself to his contribution to evolutionary biology, and shall forget that he was the founder of ecology and ethology, and made significant contributions to geology and psychology. It was, after all, his formulation of the theory of evolution by natural selection that was decisive.

In recent years there have been claims in the daily press, on television, and by retired cosmologists - that Darwin may have got it wrong. Some excuse can be found in the fact that Darwin has indeed been criticized by scientists working in a variety of fields - for example palaeontology, taxonomy and embryology. At least one group of scientists has claimed that a new evolutionary paradigm is on the way. However, to see Darwinism as being under serious threat would, I think, be a false perception. The error arises because Darwin's theory is so central to modern biology that any new idea may first be seen (as Mendelian genetics was seen) as being in conflict with Darwinism.

Let me first give a brief history of evolutionary ideas since Darwin. In the Origin of Species, Darwin aimed to establish two things. First, he argued that evolution had in fact happened (that is, that all existing organisms are descended from one or a few simple ancestral forms), and, second, that the main cause of evolutionary change was the natural selection of variations that were in their origin non-adaptive. The main weaknesses of his position were that he had no adequate theory of genetics, and that he could give no satisfactory account of the origin of the variations on which selection would later act. In genetics, Darwin was a Lamarckist. That is, he thought that if organisms acquired characteristics by use and disuse during their lifetimes, this would influence the nature of their offspring. In thinking this, he was sharing an opinion held by almost all his contemporaries.

The first major advance after Darwin was made by August Weismann, who

argued for the independence of the 'germ line' (the cell lineage leading from the fertilized egg to the germ cells, egg and sperm, which form the starting point of the next generation) from the 'soma' (the cell lineage from fertilized egg to adult body). As a boy, I acquired, from reading the preface to Shaw's *Back to Methuselah*, a picture of Weismann as a cruel and ignorant German pedant who cut the tails off mice to see if their offspring had tails. What a ridiculous experiment! Since the

mice did not actively suppress their tails as an adaptation to their environment, no Lamarckist would expect the loss to be inherited. Much later, I discovered that Weismann was not as I had imagined him. His experiment on mice was performed only because, when he first put forward his theory, he was met with the objection that, (as was, it was claimed, well known) if a dog's tail is docked, its children are often tailless — an early use of what J.B.S. Haldane once called Aunt Jobisca's theorem, 'It's a fact the whole world knows'.

Much more interesting are Weismann's reasons for proposing his theory, and its implications for Darwinism. At first sight, his reasons were poor. It is often not the case (for example, in higher plants) that the germ line is a lineage distinct from the soma. Even when it is distinct, the material

and energy it needs are supplied by the soma. In Weismann's day, the experimental evidence for the 'non-inheritance of acquired characters' was weak. Why, then, did he believe it? I think that the clue lies in his remark that, if one were to come across a case of the inheritance of an acquired character, it would be as if one were to send a telegram to China and it arrived translated into Chinese. This is the first use known to me of the information analogy in heredity. Weismann did not accept the inheritance of acquired characters because he could not conceive of a mechanism of 'reverse translation', whereby the hypertrophied muscles of the blacksmith could be translated into genes (he called them 'ids') which could, in the next generation, cause the growth of large muscles.

If Weismann was right, this greatly strenghthened Darwin's theory. Natural selection, instead of being just one of the possible processes leading to evolutionary adaptation, becomes the only process (at least, until the evolution of organisms sufficiently intelligent to learn from their parents).

The next important step was the rediscovery of Mendel's laws at the start of this century, and the formulation of the chromosome theory of heredity. The first impact of Mendelism on evolutionary biology was distinctly odd. The early Mendelians saw themselves as anti-Darwinians; Darwin's banner was held aloft by the biometric school, who concentrated on measuring the correlations between relatives, and who regarded genes as metaphysical entities. The Mendelians saw the 'mutations' they studied as each being the potential starting point of new species, and the continuous variation studied by the biometricians as evolutionarily irrelevant; the biometricians saw mutations as pathological deviants doomed to early elimination by selection, and continuous variation as the stuff of evolution. The argument, led by Bateson on the one side, and Pearson on the other. foreshadowed the current debate between punctuationists and gradualists. It is part of the larger debate between those who see the world as continuous and those who think it proceeds in jerks.

The debate, at least in the form in which it then presented itself, was largely settled by the work of the population geneticists,

NATURE

THURSDAY, APRIL 27, 1882

CHARLES DARWIN

ERY few, even among those who have taken the keenest interest in the progress of the revolution in natural knowledge set afoot by the publication of the "Origin of Species"; and who have watched, not without astonishment, the rapid and complete change which has been effected both inside and outside the boundaries of the scientific world in the attitude of men's minds towards the doctrines which are expounded in that great work, can have been prepared for the extraordinary manifestation of affectionate regard for the man, and of profound reverence for the philosopher, which followed the announcement, on Thursday last, of the death of Mr Darwin.

Not only in these islands, where so many have felt the fascination of personal contact with an intellect which had no superior, and with a character which was even nobler than the intellect; but, in all parts of the civilised world, it would seem that those whose business it is to feel the pulse of nations and to know what interests the masses of mankind, were well aware that thousands of their readers would think the world the poorer for Darwin's death, and would dwell with eager interest upon every incident of his history. In France, in Germany, in Austro-Hungary, in Italy, in the United States, writers of all shades of opinion, for once unanimous, have paid a willing tribute to the worth of our great countryman, ignored in life by the official representatives of the kingdom, but laid in death among his peers in Westminster Abbey by the will of the intelligence of the nation.

It is not for us to allude to the sacred sorrows of the bereaved home at Down; but it is no secret that, outside that domestic group, there are many to whom Mr Darwin's death is a wholly irreparable loss. And this not merely because of his wonderfully genial, simple, and generous nature; his cheerful and animated conversation, and the infinite variety and accuracy of his information; but because the more one knew of him, the more he seemed the incorporated ideal of a man of science. Acute as were his reasoning powers, vast as was his knowledge, marvellous as was his tenacious industry, under physical difficulties which would have converted nine men out of ten into aimless invalids; it was not these qualities, great as they were, which

impressed those who were admitted to his intimacy with involuntary veneration, but a certain intense and almost passionate honesty by which all his thoughts and actions were irradiated, as by a central fire.

It was this rarest and greatest of endowments which kept his vivid imagination and great speculative powers within due bounds; which compelled him to undertake the prodigious labours of original investigation and of reading, upon which his published works are based; which made him accept criticisms and suggestions from any body and every body, not only without impatience, but with expressions of gratitude sometimes almost comically in excess of their value; which led him to allow neither himself nor others to be deceived by phrases, and to spare neither time nor pains in order to obtain clear and distinct ideas upon every topic with which he occupied himself.

One could not converse with Darwin without being reminded of Socrates. There was the same desire to find some one wiser than himself; the same belief in the sovereignty of reason; the same ready humour; the same sympathetic interest in all the ways and works of men. But instead of turning away from the problems of nature as hopelessly insoluble, our modern philosopher devoted his whole life to attacking them in the spirit of Heraclitus and of Democritus, with results which are as the substance of which their speculations were anticipatory shadows.

The due appreciation or even enumeration of these results is neither practicable nor desirable at this moment. There is a time for all things—a time for glorying in our ever-extending conquests over the realm of nature, and a time for mourning over the heroes who have led us to victory.

None have fought better, and none have been more fortunate than Charles Darwin. He found a great truth, trodden under foot, reviled by bigots, and ridiculed by all the world, he lived long enough to see it, chiefly by his own efforts, irrefragably established in science, inseparably incorporated with the common thoughts of men, and only hated and feared by those who would revile, but dare not. What shall a man desire more than this? Once more the image of Socrates rises unbidden, and the noble peroration of the "Apology" rings in our ears as if it were Charles Darwin's farewell:—

"The hour of departure has arrived, and we go our ways — I to die and you to live. Which is the better, God only knows." T.H. HUXLEY

Fisher, Haldane and Wright. Two points were made clear. First, the continuous variation studied by the biometricians could be explained by alternative alleles at many loci, each by itself having a small effect on the phenotype. Second, even rather small differences in fitness between genotypes are sufficient to determine the direction of evolutionary change, despite mutation being mainly in an opposition direction.

The work of the population geneticists prepared the way for the 'modern synthesis' of evolutionary biology, developed in the period 1930–1950 by a group including Dobzhansky, Ford, Julian Huxley, Mayr, Muller, Rensch, Simpson and Stebbins. It is hard in a few sentences to describe what these men did. In effect, they showed that the 'neo-Darwinian' mechanism — natural selection in Mendelian populations — was sufficient to explain the evolutionary process as it could be observed in nature. Dobzhansky, Ford and others measured genetic variability and natural selection in wild populations.

Mayr and Rensch (for animals) and Stebbins (for plants) studied geographical variation within and between species, and discussed how new species might arise. Simpson aruged that the fossil record could best be understood in Darwinian terms. Most research in evolutionary biology since that time has been carried out in the framework of the modern synthesis. Particular efforts have been made in areas which, at least at first sight, seem to be difficult to explain in terms of natural selection, for example, the evolution of social behaviour and of sex and breeding systems.

Since 1950, developments in molecular biology have had a growing influence on the theory of evolution. The 'central dogma' of molecular biology, according to which information can pass from nucleic acid to protein, but not from protein to nucleic acid, provides a molecular explanation for Weismann's principle, thus leaving natural selection as the only agent of adaptation. Important as this is, however, two additional points should be

made. First, even if 'reverse translation' of amino acid sequences into base sequences were possible, this would not provide a general mechanism for Lamarckian inheritance, because most developmental adaptations do not involve the production of new protein sequences. Second, there are good reasons why, even if living organisms have arisen independently many times in the universe, Lamarckian processes should play a minor role in their evolution. Most 'acquired characters' are non-adaptive they are the results of age, injury and disease. Therefore, a hereditary mechanism which transmitted such characters to offspring would work against the evolution of adaptation. Hence the one-way flow of information from nucleic acid to protein may have been a necessary feature of an hereditary mechanism able to support evolution. In physics, the second law of thermo-dynamics asserts that entropy will increase in a closed physical system. In biology, Weismann's principle, together with the principle of natural selection, makes possible the maintenance,

and even the increase, of information in open biological systems.

Molecular biology has had an impact on evolutionary theory in other ways. Protein electrophoresis has provided a way of measuring the genetic variability of populations; its main value may be in enabling us to discover more about the breeding structure of populations. Sequence data on proteins and nucleic acids can be used to work out the phylogenetic relationships of existing organisms. In this context, sequences have the advantage over morphological data in that they provide a means of estimating the number of genetic changes separating two forms. The information we are acquiring about how DNA is arranged in chromosomes may at last give us some insight into the evolutionary significance of chromosome structure. Two questions in particular are being asked. First, does the large-scale arrangement of genes on chromosomes have any significance for development, or is it merely a way of ensuring accurate gene segregation during cell division? Second, does all the DNA in the genome perform some useful function in the survival or reproduction of the organism, or is some part of it 'selfish' or 'parasitic'? The second question raises a set of problems which are logically similar to those which have been debated for some time by students of the evolution of social behaviour, that is, questions about the levels at which selection acts and the differences between what Dawkins has called 'replicators' and 'vehicles'.

There is, however, one area of molecular biology which seems to me to lag behind the rest. This is the study of the evolution of prokaryotes (organisms such as bacteria lacking a proper cell nucleus). The modern synthesis of the 1940s was concerned with eukaryotes (organisms with a cell nucleus, usually sexual and diploid). Its essential achievement was to bring together two previously separate disciplines — the chromosome theory of heredity and the study of natural populations. The same synthesis is now required for the prokaryotes. There is an abundant knowledge of their genetics, but as yet no adequate synthesis of that knowledge with a study of the natural history of bacteria. For example, we have little idea of the significance of conjugation for bacterial populations; it is as if we had no idea of the significance of sexual reproduction for populations of birds or insects. Population thinking has been well developed for fully half a century, but has yet to be adopted by microbiology.

This essay is an abbreviated version of the introduction to Evolution Now, a collection of recent papers on controversial issues in evolution with commentaries by John Maynard-Smith. Evolution Now is being published by Macmillan Press and, in the USA, by W.H. Freeman. It will be available to Nature subscribers as advertised in next week's issue.

THE LATE MR. DARWIN.

The Times. 3 May 1982

At the scientific meeting of the Zoological Society, vesterday evening, before the commencement of the proceedings, the president, Professor Flower said. - The minutes read recall the fact that at our last meeting we were honoured by a communication from Dr. Darwin, probably his last contribution to that science to which he devoted his life-long labours. No one who heard that paper, showing as it did no sign of faltering from that eager interest which he had always manifested in a subject which he had made peculiarly his own, expected that not 24 hours would elapse before those labours would be brought to a close. During the fortnight that has passed the whole world has been moved at the loss it has sustained, and his work and his character have, more than any other theme, filled the minds of thinking people of all countries, classes, creeds, and occupations. We who humbly follow him in cultivating the science he adorned must feel elevated at the sight of the full recognition accorded to his work. The general acceptance of Darwin as one who has exercised a powerful influence upon the whole realm of human thought, the cordial reception of his remains in our magnificent Abbey, among the illustrious men of whom our country is proud, are triumphs in the history of zoology, for it was mainly zoological observation which led to those philosophical speculations which have made his name famous. The nation's grief at his loss has already found eloquent and feeling expression in many quarters; the resources of our language seem to have been exhausted in bearing testimony to his worth. No words that I could find would add anything to what has been so well said by others; and surely here, if an any place in the world, among those who are always occupied with subjects the pursuit of which has been so profoundly modified by his writings, and among many who loved him as a personal friend, nothing is needed but to mention his name to call forth the strongest feelings of admiration for his work and reverence for character. If it is not given to any of us to: emulate him in brilliancy of scientific induction, or to light upon discoveries that will change the current of human ideas, we can at least endeavour to follow the example he has set us of patient perseverance in observation, scrupulous accuracy of statement, deference for the opinions and feelings of others, candour towards opponents, and of that invariable modesty and gentleness of demeanour which shed such a charm around his public as well as his private life.

LATEST INTELLIGENCE

(FROM OUR CORRESPONDENTS.)

(BY TELEGRAPH.)

FRANCE.
PARIS, MONDAY, APRIL 24 Mr. Darwin has to be added to the long list of eminent men, not excluding Catholic prelates, whom the Univers has denounced or deemed. Its wrath has been excited by the praises of the Radical Justice. The notices in the French Press, by the way, have mostly been very

meagre. It thus winds up two columns of sarcasm:

"When hypotheses tend to nothing less than the destruction of faith, the shurring out of God from the heart of man, and the diffusion of the fifthy leprosy of Materialism, the savant who invents and propagates either a criminal or a fool. Viola ce que nous avons à dire du

The Times, 25 April

TO THE EDITOR OF THE TIMES

Sir,-May I beg a corner for my feeble testimony to the marvellous persevering endurance in the cause of science of that great naturalist, my old and lost friend, Mr. Charles Darwin, whose remains are so very justly to be honoured with a resting-place in Westminster Abbey

Perhaps no can better testify to his early and most trying labours than myself. We worked together for several years at the same table in the poop cabin of the Beagle during her celebrated voyage, he with his microscope and myself at the charts. It was often a very lively end of the little craft, and distressingly so to my old friend, who suffered greatly from sca-sischess. After, perhaps, an hour's work he would say to me.
"Old fellow, I must take the horizontal for it," that being the best relief
position from ship motion; a stretch out on one side of the table for ome time would enable him to resume his labours for awhile, when be

It was distressing to witness this early sacrifice of Mr. Darwin's health, who ever afterwards seriously felt the ill-effects of the Beagle's

J. LORT STOKES, Admiral. Scotchwell, Pembrokeshire, April 25. Lam, Sir. yours truly

The Times, 27 April

CHARLES ROBERT DARWIN

Exactly a year to a day has separated the deaths of two of the most powerful men of this century, some have said of any century; and those who care for the task will find some very curious analogies between the progress and the ultimate results of the work of the two men, totally different as were the spheres in which they exercised their remarkable powers. On April 19, 1881, all the civilized world held its breath at the new of the death of Lord Beaconsfield; not less must be the effect upon the most civilized part of the civilized world when the announcement of the death of Charles Darwin flashes over the face of that earth whose secrets he has done more than any other to reveal. All who knew anything of Mr. Darwin know that, massive as he seemed, it was only by the greatest care and the simplest habits that he was able to maintain a moderate amount of health and strength. Mr. Darwin had been suffering for some time past from weakness of the heart, but had continued to do a slight amount of experimental work up to the last. He was taken ill on the night of Tuesday last, wher he had an attack of pain in the chest with faintness and nausea. The latter lasted with more or less intermission during Wednesday and culiminated in his death, which took place a about 4 o'clock on Wednesday afternoon. He remain conscious to within a quarter of an hour of his death. His wife and several of his children were present at the closing scene During his illness he had been attended by Dr. Norman Moore, Dr. Andrew Clarke, Dr. Moxon, and Dr. Alfrey, of St. Mary Cray.

Fifteen volumes lie before us and nearly as many memoir large and small, the product of 45 years' work - a produc hich, in quantity, would do credit to the most robust constitution. But when we consider Mr. Darwin's always feeble health and his deliberately slow method of work, never hasting but rarely resting, the result seems marvellous. But wonderful as this is under the circumstances, it is not by mere quantity that Mr. Darwin's work will be judged: the quantity is of chief importance in respect of the multifarious channels through which his influence has spread.

The Times, 21 April

NEWS AND VIEWS

Methylation and gene control

from Gary Felsenfeld and James McGhee

ARE changes in DNA methylation patterns a cause or an effect of eukaryotic gene expression? There are already many examples of an inverse correlation between the level of methylation in the neighbourhood of a gene and the transcriptional activity of that gene. It is more difficult to prove that the extent of methylation is in itself sufficient to determine gene activity.

Several recent studies tackle this problem by making use of the inability of bacterial restriction endonucleases to cleave DNA restriction sites that have been methylated. In eukaryotes, the site of methylation is almost invariably the 5' position of cytosine and, in animals, the cytosine residue is usually contained in the sequence CpG. The restriction endonucleases HpaII and MspI, which can cut the sequence CCGG, have therefore proved useful tools in these studies1. Methylation renders the sequence resistant to the Hpall endonuclease, but not to Mspl, and with the use of gel electrophoresis and Southern blotting, the pattern of methylation at those CpG sites which are embedded in a CCGG sequence can be determined in some detail.

It has been shown with these (and other) restriction enzymes that certain CpG sites in the vicinity of a wide variety of genes are undermethylated in a tissue in which the gene is expressed compared with a tissue in which the gene is inactive (reviewed in ref. 2). Unfortunately, only a fraction of methylation sites are also restriction sites and can be detected in this way. The pattern of variation in methylation is complex, and usually does not involve complete demethylation of extensive regions of the DNA, although the pattern tends to be stably inherited within a given cell line. This is presumably because the enzyme bringing about methylation acts much more efficiently on hemimethylated sites than on unmethylated ones, and therefore methylates the daughter strand of a newly replicated duplex wherever the parent strand is methylated.

To show that DNA methylation directly affects gene expression requires an experimental method of altering methylation levels. Recently the *Hpall* methylase has been used to introduce methyl groups into defined DNA sequences. In early studies^{3,4}, the herpes thymidine kinase (tk) gene was methylated in vitro and used to transform mouse LtK-

cells. Methylation decreased the transformation efficiency. and transformants selected for tk expression carried tk sequences that were partially demethylated relative to the input DNA. Though these results are compatible with an inhibitory effect of methylation on tk expression, their interpretation is complicated by the possible effects of methylation on the transformation process itself. Such effects cannot be measured because apparently only cells carrying at least partially demethylated tk sequences survive.

A new experiment by Stein et al. 5 solves the problem by using separate genes for selection and for methylation. Mouse Ltkaprt- cells were transformed with herpes tk DNA, and in addition co-transformed with hamster aprt (adenine phosphoribosyl transferase) DNA. The aprt gene was introduced either in the unmethylated form or after methylation in vitro by Hpall methylase. Clones selected for tk+ activity were then assayed for expression of the cotransformed but unselected aprt gene. (It has been shown earlier6 that methylation patterns of transforming sequences not subject to selection pressure are stable over many generations.) Clones transformed with unmethylated aprt sequences were found to express the aprt gene. Clones transformed with methylated aprt neither transcribed nor expressed the gene, even though the methylated sequences could be detected within the transformed cells by Southern blotting, and appeared to be incorporated into the genome with an efficiency similar to that for unmethylated aprt sequences. When the clones carrying methylated aprt were subjected to conditions selecting for the aprt+ phenotype, reversion was found to be associated with undermethylation of the aprt sequences. The authors conclude that the observed effect of methylation on aprt activity arises from a direct influence of methylation on gene expresion.

The connection between DNA methylation and gene expression is supported by studies of mouse retroviruses. A number of workers had previously shown that the inactive, gene-

Gary Felsenfeld and James McGhee are in the Laboratory of Molecular Biology, NIADDK National Institutes of Health, Bethesda, MD 20205. tically acquired proviral sequences are heavily methylated whereas the active, somatically acquired copies are undermethylated. In a recent study, Stuhlmann et al.⁷ used transfection of cell cultures by purified mouse DNA to show that the nonmethylated proviral sequences were infectious whereas the methylated sequences were not. Furthermore, a copy of the endogenous inactive provirus was cloned in bacteria and the cloned DNA (now unmethylated at CpG sites) was found to be highly infectious⁸.

A possible objection to DNA transfection and transformation studies is that cytosine methylation could direct the site of DNA integration. For example, methylated DNA could integrate into methylated regions of the chromosome, which are inactive for other reasons. Perhaps this objection could be overcome by more detailed studied of flanking regions or by transformation with methylated and unmethylated sequences ligated together in the same molecule. In any case, a methyl-directed integration model cannot explain the results of Vardimon et al.9. A region of adenovirus coding for the Ad2-specific DNA binding protein was cloned and the DNA, either left unmethylated or methylated in vitro with the Hpall methylase, was injected into Xenopus oocytes. The results were striking: unmethylated DNA produced adenovirus-specific RNA, whereas the methylated DNA did not.

Levels of methylation can also be deliberately altered by the use of the nucleoside analogue 5-azacytidine (5-azaC), which inhibits DNA methylation in vivo. Jones and Taylor¹⁰ have shown that 5-azaC can induce differentiation in cultured mouse embryo cells, and that at the same time and dosage the cellular DNA becomes demethylated. Three other cytidine analogues behave similarly, whereas two more that do not induce differentiation do not affect methylation. Two recent studies have extended this approach to an analysis of the state of individual genes after cell growth in 5-azaC. Groudine et al. 11 report that 5-azaC induces expression of an endogenous avian retrovirus, and that this expression is associated with both DNA demethylation and increased nuclease sensitivity of the viral sequences in chromatin. Compere and Palmiter12 have studied the effect of 5-azaC on the

expression of the metallothionein gene in a mouse thymoma cell line in which the gene is normally uninducible. After exposure to 5-azaC, sites on the gene are unmethylated and the gene becomes inducible. Finally, 5-azaC has been used to enhance the reactivation of the inactivated human X chromosome in mouse-human cell hybrids13, an effect consistent with the proposal that DNA methylation is the basis of X chromosome inactivation in female mammals13,14.

The mechanism by which 5-azaC causes demethylation is unclear. The analogue apparently must be incorporated into DNA to inhibit methylation^{10,12}, but it cannot function merely by virtue of a lack of a methylatable atom in the 5 position, since the extent of demethylation far exceeds the amount of 5-azaC incorporation. Furthermore, not all genes can be activated by non-lethal concentrations of 5-azaC^{5,15}, perhaps because activation of some genes requires more extensive demethylation than can be achieved with non-toxic levels of 5-azaC. There is evidence that methylase can act as a processive enzyme, so that a single 5-azaC in a daughter DNA strand could affect the methylation of cytosines downstream on that strand. If binding of methylase in vivo were coupled to replication, the effect of 5-azaC on gene expression could be a complicated function of the distance between the methylatable control region of the gene and the nearest replication origin.

Although methylation levels are clearly correlated with expression in the cases discussed above, there are some genes, even in organisms with a high general level of DNA methylation, that do not display such obvious correlations. For example, the $\alpha(2)I$ collagen gene of chicken has a pattern of HpaII site methylation that is invariant (with some sites completely unmethylated) in five cell types that have been studied, whether or not the cell type synthesizes detectable amounts of collagen16. Another anomaly has been reported in the case of X chromosomes from normal human cells, which in contrast to X chromosomes from mousehuman cell hybrids reveal no simple correlation between chromosome inactivation and the pattern of methylation at Hpall sites. Although these may be examples of situations in which control of expression is not coupled to altered levels of methylation, it is also possible that the crucial methylation sites are not Hpall sites.

In any case, these results are not inconsistent with models in which absence of methylation at specific residues is necessary for gene expression. Analysis of existing data suggests that the methylation sites critical to a given gene's control processes may be a small fraction of those sites present in that DNA region. The effect of methylating these critical sites presumably is be to alter the way in which proteins interact with the region, either by

modifying local interactions with the active sites of sequence-specific proteins, or by longer-range effects on DNA structure. In the synthetic polynucleotide poly(dC-dG). poly(dC-dG), which consists entirely of CpG repeats, methylation of the cytosine residues causes the polymer to adopt the left-handed Z DNA conformation under physiological salt conditions¹⁷. Furthermore, the Z form has so far proven incapable of forming nucleosomes¹⁸. Such results lead quite naturally to the idea that methylation in vivo may have a major effect on DNA and chromatin structure, but one should not try to be too specific, at this stage, concerning the nature of such effects. There is, for example, at the 5' end of the chicken adult β globin gene a region 200 base pairs long, which contains about six times the genomic frequency of CpG sites, and which is exposed, apparently nucleosome free and reduced in methylation when the globin gene is active19. Examination of the nucleotide sequence does not, however, reveal any extended sequence of alternating purines and pyrimidines of the kind required for Z DNA formation, so that the effects (if any) of methylation on the structure of this region are likely to be more subtle.

Although it now appears that DNA methylation plays an important role in gene expression during development, it should be recalled that some organisms (notably insects) manage quite well without any extensive methylation. The mechanisms for marking expressed genes in such organisms, like the mechanism that marks genes for demethylation in the organisms discussed above, remains unknown.

Vitamin A, limb patterns and the search for the positional code

from Jonathan Cooke

By around 1940 such figures as Boveri, Harrison, Child and Spemann had propounded, in essence, all the rival scientific theories that we have subsequently lived with concerning animal morphogenesis, with its reliable and typical spatial patterns of cellular differentiation. There has followed a wealth of phenomenological work fleshing out one or another of these theories, and resulting in refinement or renaming of ideas according to the allegiances of the workers concerned.

But this has been accompanied by so little progress towards real knowledge of the biological machinery of development that some scientists see the efforts of the last forty years as taking place in a world like that of Herman Hesse's allegorical novel 'The Glass Bead Game', where compulsive scholars are forever playing a purely internal and, by prearrangement, interminable game with the pieces of theories. A sour-minded view maybe, but the sad fact is that the various conjectures about morphogenetic mechanisms have swung in and out of fashion over the years in a way that would be more appropriately explained by microsociologists or social historians of science than by the scientists themselves.

As an addicted insider I report the embryological glass bead game to be still alive and compulsively enjoyable, but can nevertheless see the present force of argument for a swing towards a more reductionist, biochemical approach to promote real progress. An opportunity for just this may be presented by two exciting new reports that compounds of the vitamin A family exert systematic effects upon the anatomical patterns of developing and regenerating limbs. The effects are separable from uninformative toxicity, and involve formation of elements of the familiar patterns that are in themselves histologically normal, but in quite abnormal spatial configurations.

In one case Maden1 shows that regeneration from the amputated limb stump of an amphibian is disturbed when its early phases are delayed by the presence of retinoic acid or its derivatives in the bathing medium. The terminal population of locally de-differentiated cells or

Jonathan Cooke is in the MRC National Institute for Medical Research, The Ridgeway, Mill Hill, London NW7 1AA.

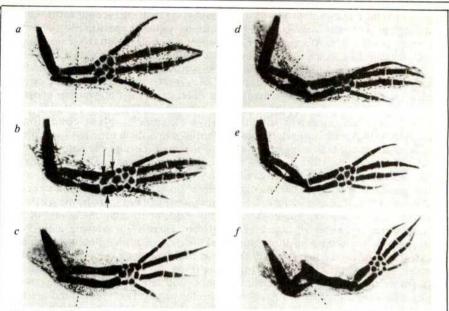

blastema, from which the regenerate develops, normally differentiates to replace just that part of the base-to-tip sequence that was removed by amputation. In Maden's experimental cases, it reiterates an inappropriately large part of this baseto-tip sequence, so that the limb finally regenerated has internal pattern repetition in the long axis. The precise level in the pattern from which the blastema cells now re-commence differentiation, and thus the extent of the final repetition, depends largely on the level of amputation in the original limb and the length of exposure to the vitamin over several days, rather than being a simple expression of the chemical concentration of the agent. Neither delay in initiation of regeneration due to other agencies nor, indeed, any other known manipulation can effect such 'proximalisation' of the positional values recorded in these blastema cells.

In Maden's words, these results "all contravene the rule of distal transformation", a rule that was coined to express the phenomenon that biological patterns seem characterized by an 'uphillto-downhill' polarity, such that regeneration by cells at a cut edge will normally proceed only downhill. The fact that a novel experimental circumstance, and especially a biochemical insult, can by-pass such 'rules' should not, however, surprise us. Organisms consist of evolved arrangements whereby normal processes and results have been assured given normal surrounding circumstances, whereas the pre-biotic world, so far as we know, does not. Thus while Newton might well stir momentarily should two asteroids be observed to jink away from each other as they passed in their orbits, no one coining a 'rule' or 'law' as part of a theory for biological process expects it to be proof against all future insults.

In the other case, Tickle et al. (Nature, in the press) show that early development of the bird limb bud is disturbed by implantation of a local reservoir of retinoic acid in an anterior position within it. But here, the systematic mirror duplications in the antero-posterior axis of pattern, that is, the sequence of digits that are produced, are similar to the result of implanting a particular piece of indigenous tissue — the normally posteriorly situated zone of polarizing activity — to a similar anterior position.

Even a speculative comparison of the vitamin A concentrations experienced by the reacting cells in the two systems is difficult, but in the bird experiments², the local concentration near the source, and perhaps in the entire limb, may be an order of magnitude higher than the upper end of the ambient concentration range in the regeneration study¹. The length of time for which it is present in the limb buds, in relation to the days-long exposure of the blastemas, is unknown (or at least not stated).

It is, at first, astounding that separate

The limbs shown above regenerated after amputation through the mid-radius and ulna (broken line). The distal radius, and ulna, carpals and digits have all been replaced. (a) A control limb which regenerated in pure tap water (b-e) Limbs treated with 15IU ml⁻¹ retinol palmitate for 12 days. In each case pattern elements were added; (b) contains extra carpal-like cartilage; (c) an abnormal length of radius and ulna; (d) a complete extra radius and ulna and (e) duplication as far back as the distal end of the humerus and including a perfect elbowjoint. In (f) a complete limb has been produced, distal to the amputation plane, by exposure to a higher concentration of retinol palonitate (15 days in 75 IUml⁻¹).

Increasing the concentration or time of exposure to retinol palmitate causes the level from which the limb was repeated to become more and more proximal until finally a complete limb is regenerated from the amputation plane. When the position of the amputation plane is varied it is found that higher levels of retinol palmitate are needed to regenerate complete limbs from more distal positions; only the highest concentration at the longest time produced regeneration of a complete limb from the carpal level.

dimensions of the anatomical pattern are exclusively affected in each system, when they are, after all, homologous episodes of pattern formation in related organisms. The entire enterprises of comparative anatomy and causal embryology can, however, be rescued if one chooses to deduce, from other data available, that pattern axes in the present experiments are affected according to whether or not, in each system, certain spatial interactions are possible along them (that is, whether they are in what embryologists refer to as the labile or the mosaic state) at the time of exposure.

Unpublished work at the National Institute of Medical Research suggests that ambient exposure, rather than localised sources, in the chick limb, affects the antero-posterior pattern axis, which is the labile one at the time, but does not cause duplications. So one very abstract scheme would be that proximal and posterior boundaries of the pattern represent 'source' or 'origin' states, and that excess vitamin drives cells progressively and artificially towards these regardless of the state previously dictated by their position. During limb outgrowth, the proximo-distal sequence of pattern contributions evolves locally in the cell population of the tip by means of time itself, time which can be 'set back' by means of simple exposure to the compound. In anterior-posterior pattern formation in the chick limb, by contrast,

polarity has normally to be maintained across a zone of tissue one millimetre wide where the cells are still labile. This is accomplished by prolonged signalling, from a localized source, the zone of polarizing activity. Hence the requirement for a localized reservoir of the experimental agent to provoke a new boundary elsewhere and thus duplication.

But almost nothing can be deduced from the present observations simply by plugging them into current detailed but abstract models, involving such entities as separable cell positional values and 'interpretation' processes, pre-patterns, progress zones, serial inductions and so on (see for example, refs 3-5). All such schemes are, at best, simply consistent with, rather than positively dictated, by the phenomena they have sought to explain, and with the hindsight of final understanding they might even come to be seen as having impeded, rather than helped, attempts to understand effects such as that of retinoic acid.

Anyone who would make sense of the new phenomena had better be prepared to be involved with protein gels, fractionation columns and membrane preparations, for surely the genuine excitment is in the promise they hold out for biochemical investigation of pattern control in appropriate experimental material, via our imperfect knowledge of the loci at which vitamin A inserts itself into the metabolic

functions of the cell. One can only hope for sustained effort rewarded by good luck in any such assisted guessing games, for it would be sad if the present results fared no better than the 'lithium phenomenon'.

Lithium is the best known of a small. chemically diverse group of simple substances, long ago discovered to have systematic distorting effects, this time on primary proportioning of the whole body pattern at its first determination, in ways which are 'homologous' in a wide variety of embryo types. The effects are of the same order of specificity as the present ones. They must be telling us something about the biochemistry or cell biology of spatial organization^{6,7}, but no-one has ever discovered what. Lithium ions, substituting for, and thus distorting, the role of sodium as they presumably do, may affect so many membrane and other functions that the domain to be searched for the relevant effect is very great. We might hope for more success with retinoic acid with its more restricted list of functions. Mediation in the glycosylation of proteins, effects upon gap junction formation and upon the balance of secreted matrix proteins have been mentioned in the publications. These molecular assemblies have each been previously suggested as candidates for involvement in the setting up or maintenance of tissue positional codes.

T cells immortalized?

from Nigel Williams

SUCCESSFULLY fuse an antibodyproducing B cell with a myeloma cell and there is a good chance that the resulting hybridoma will provide a continuous supply of monoclonal antibodies. Can similar techniques be applied to T cells, the other major population of lymphocytes within the immune system, whose function is much less well understood? The answer that emerged from a recent meeting in Basel* is that in many cases it can. T cells are a functionally heterogeneous population of cells whose antigen-specific surface or soluble receptor molecules remain a puzzle, so the production of functional T-cell hybridomas to provide a monoclonal source is clearly of great interest. How these molecules relate to antibodies and how many different molecules are produced are two major questions to which the production of hybridomas has been addressed.

The function of one major population of T cells is to help B cells produce antibodies. On stimulation by antigen presented by macrophages bearing self molecules by the major histocompatability complex (MHC), T cells can release molecules which help B cells produce antibodies against the same antigen. However, from cloning such T cells it is clear that on stimulation they can also release other factors. Interleukin-2, also known as T-cell growth factor (TCGF), is the best characterized and can stimulate the growth of resting T cells. Stimulated helper T cells can also provide bystander help, that is, they can stimulate antibody production by B cells regardless of their specificity. How this function is achieved is not understood.

M. Schreier (Basel Institute for Immunology) has produced clones of mouse helper T cells generated against egg albumin (EA). While all the clones could provide all these functions, the amount of help for antibody responses against EA and TCGF production varied greatly between different clones and neither of these functions correlated with the amount of bystander help. He has produced hybridomas from these cloned T cells which also preferentially expressed different functions. Although it is not yet clear how far these differences in helper function result from quantitative differences in the production of similar molecules, and how far from differences in the molecules produced, stable factorproducing hybridoma clones should eventually help resolve these questions.

Many of the characteristics of mouse helper T cells have been confirmed in human ones. E. de Freitas (Wistar Institute, Philadelphia) has produced hybridomas between human helper T cells generated against tetanus toxoid and a human T-lymphoma cell line which produce TCGF and also help B cells produce antibodies against tetanus toxoid. As in mice, the expression of these two functions varied in different hybridoma clones. It is not known whether these cells can also produce bystander help but if they do, then the exciting possibility is raised that human antibodies could readily be produced in vitro.

A second population of T cells functions

F

Nigel Williams is a member of the editorial staff

of Nature.

to suppress antibody production. Hybridomas have provided a monoclonal source of the molecules involved. Although, like antibodies, these molecules carry an antigen-binding component, some also appear to carry determinants encoded by the I region of the MHC. However it is not clear whether antigen binding and I-region determinants are found on a single polypeptide chain.

M. Taniguchi (Chiba University) described recent work on hybridoma clones producing a suppressor factor specific for the antigen keyhole limpet haemocyanin (KLH), expressing I-J-region determinants. This could be extracted from the hybridoma cells or obtained in the ascites from hybridoma-bearing mice as a secreted factor. By use of immunoabsorbent columns he showed that the activity of the extracted factor could be reconstituted by mixing equal proportions of eluates from an anti-I-J column and a KLH column. If the secreted factor was first subjected to reducing conditions, similar reconstitution of activity could be obtained by mixing eluates from these two columns. This evidence for a two-chain factor is supported by experiments in which mRNA extracted from the hybridomas was injected into Xenopus oocytes where it was translated. The mixture of equal quantities of two translocation products showed strong suppressor activity with KLH specificity, while either product alone was without effect.

D. Webb (Roche Institute of Molecular Biology, Nutley) has also produced T-suppressor cell hybridomas, but specific for the synthetic polypeptide GAT, in two different strains of mice. One of these strains can respond and produce antibody following challenge with the antigen, whereas the other (non-responder) strain is unable to produce anti-GAT antibody. However specific suppressor T-cell releasing factors can be found in both mice. These have been highly purified from the hybridomas and one has recently been reported (Proc. natn. Acad. Sci. U.S.A. 97, 1254; 1982). (Such a feat demonstrates the importance of a monoclonal source to obtain 2 mg of factor, 10 litres of supernatant were required. Slightly better yields were obtained from the extracted factor.)

It has been shown that these molecules have an antigen-binding region and carry I-J-region-encoded determinants. However it seems that the factor from the non-responder mice is a single polypeptide while in the responder strain there are two different factors: one a single-chain and the other a two-chain polypeptide. Cloned cDNA encoding these molecules has now been produced and should provide further illumination.

In another system where suppressor T cells control the contact sensitivity response to the hapten nitrophenol, M. Dorf (Harvard University) described a series of three interacting suppressor cell

^{*}A meeting on T-cell hybridomas was organized by and held at the Basel Institute for Immunology, 27-29 January 1982.

types which release factors, from which hybridomas have been produced. Again such factors carry *I-J*-region determinants and have antigen-binding (or in the case of the second type TsF_2 , idiotype-binding) specificity. Preliminary experiments from immunoabsorbant columns were described which showed that the activity of TsF_2 could be reconstituted from equal amounts of eluates from an anti-idiotype column and anti-*I-J*-column following treatment of the factor under reducing conditions. This suggests that this factor in the series consists of two chains linked by a disulphide bond.

As T-cell hybridomas provide a monoclonal source of an increasing array of molecules it is crucial that their function is clearly established. Stressed by J. Miller, this point is underlined by a recent report by D. Capra (Pacifico & Capra J. exp. Med. 152, 1289; 1980). He originally claimed (Clark & Capra J. exp. Med. 155, 611; 1982) to have produced a hybridoma clone releasing an antigen-specific suppressor factor bearing I-region-encoded determinants. However the factor was not functionally tested and it now appears that the molecule can be recovered from lysates of other unrelated cells, although it is not yet known if this molecule carries I-region determinants.

The function of the T-cell molecules is one of the central questions facing immunologists; the other is that of their relationship to antibodies. The antigen-binding portion of an antibody molecule is encoded by a group of variable region genes. The rest of the molecule is encoded by constant region genes (those for the heavy chain determine the class of antibody). It is not yet clear whether the antigen-binding region of the T-cell molecules is encoded by antibody variable region genes. Some seem to bear variable region determinants while others do not.

Possible evidence for constant region determinants was described by E. Culbert (University College London). He has produced hybridomas from antigenspecific helper and suppressor T cells. Rabbit antisera raised against these factors appear to be able to descriminate between helper and suppressor hybridomas regardless of antigen specificity. Taniguchi has antisera that seem to detect a constant region determinant on the antigen-binding chain of his two-chain suppressor molecule. These seem to be encoded by genes close to the heavy chain constant region genes of antibody, as the antisera, raised in antibody heavy chain congenic mice, can detect determinants selectively expressed on T cells.

It is clear that the application of hybridoma technology is helping to provide an immortalized source of T-cell molecules. Although several different antigen-specific molecules have now been produced by these means, their precise relationship to antibodies remains tantalizingly obscure.

How cells in distress use SOS

from S.G. Sedgwick and G.T. Yarranton

TREATMENT of eukarvotic and prokarvotic cells with DNA damaging agents induces a diverse and somewhat bewildering variety of cellular responses. One interpretation is that cells in general coordinately control operons which are expressed only in response to DNA damage. A model system of DNA damage-induced gene expression is the SOS response of Escherichia coli. This response entails de-repression of at least 12 different operons. The response alters DNA repair capability, mutagenesis, restriction modification and cell division control, and leads to expression of several different din genes, identified only by their inducibility by DNA damage. In addition, certain prophages, such as \(\lambda\), are de-repressed and enter a cycle of lytic growth. It has been supposed that the phages have evolved to take advantage of the SOS response so that they can abandon a host cell whose viability is uncertain.

Although the genes which are switched on participate in several metabolically distinct pathways, they appear to be part of a single regulatory unit, the SOS regulon, whose expression is controlled by the *lexA* and *recA* genes. The idea that lexA protein is a multisite repressor switching off transcription of the *recA* and several other genes, including its own, has recently gained direct support.

Little et al.2 and Brent and Ptashne3 have purified lexA protein and examined its binding to purified control sequences of the lexA and recA genes. Both DNAs contained 20 base pair palindromic sequences, or SOS boxes, which were protected by lexA protein against nuclease and methylation treatments. The recA gene has a single box, whilst the lexA gene has a tandem pair. Significantly, all three binding sites show considerable homology with one another^{2,4} and with sequences preceeding two other genes, uvrA and uvrB5,6,6A, which are also part of the SOS regulon. Repressor activity in vitro was demonstrated directly by specific inhibition of transcription from both lexA and recA promoters by purified lexA protein. Further evidence of multigenic repression by lexA protein was provided by analogous experiments in which lexA protein blocked in vitro transcription from cloned uvrB6A and dinA and dinB genes7. Thus, during normal growth, the genes of the SOS regulon would be repressed by lexA protein which would be maintained at a constant level by the autoregulatory repression which lexA protein exerts on its own synthesis.

Predictions that induction of the SOS

S.G. Sedgwick and G.T. Yarranton are in the Genetics Division, National Institute for Medical Research, The Ridgeway, Mill Hill, London NW7 1AA.

regulon is caused by proteolytic inactivation of lexA protein by recA protein have also been confirmed. Little et al. 2 showed in vitro that homogeneous recA protein cleaves purified lexA protein into two fragments that cannot repress transcription from the recA promoter. They used a mutant form of recA protein that has stronger than normal proteolytic activity, but similar proteolytic action by wild-type recA protein is thought to be activated following damaging treatments by single-stranded DNA or DNA degradation products. The proteolysis of lexA protein therefore closely resembles the \(\lambda\) repressor cleavage reaction described by J.W. Roberts and his colleagues8. Indeed, the cleavage site is in a region with a similar composition to that of λ repressor⁹ and may thus provide a molecular example of convergent evolution — λ repressor has evolved to mimic lexA protein as a substrate of proteolysis by recA protein.

Clues to how finer regulation of the SOS response occurs are also appearing. First, recA cleaves lexA protein at least ten times more efficiently than it does λ repressor. This may favour survival of λ by ensuring that lysogenic induction does not occur until the levels of DNA damage exceed the capacity of the inducible repair systems9. Second, the recA SOS box binds lexA protein about ten times more strongly than do the pair of boxes preceeding the lexA gene³. Thus, various SOS operons with different variations of the SOS box sequence may be derepressed after different amounts of lexA protein have been inactivated. The reason why there are two SOS boxes at the lexA locus is not clear, though Brent and Ptashne suggest that their lower affinity would permit de novo lexA protein synthesis during induction. As a result, the period in which lexA levels fall might be extended, permitting finer discrimination for switching on part, but not all, of the regulon. Lower repressor affinity of the lexA operator might be expected on theoretical grounds since the gene must presumably synthesize sufficient product to ensure repression of the rest of the regulon before it switches off its own expression.

Third, the relative position of SOS promoter and operator sequences vary^{2,3}. However, the importance of this feature is unclear and the relative binding constants of promoters at different sites must be determined before the complete kinetic analysis of gene expression during induction can be made.

A second refinement of the basic SOS model must be introduced to account for at least two genes which can be regulated independently, or as part of the SOS regulon. The uvrB gene, which codes for a

subunit of the UV endonuclease, was found by Fogliano and Schendel¹⁰ to be under lexA control. Subsequent sequence analysis of the uvrB control region5,6A revealed adjacent non-overlapping promoter sequences. The P2 promoter, furthest from the initiation codon, spans an SOS box⁵ protected from in vitro nuclease digestion by lex A protein, suggesting that this is the site where lexA repression occurs. Control of expression from P1 is as yet unresolved, although van den Berg et al. suggest that the uvrC protein may be involved. Interestingly, Sancar et al. 11 have identified and purified the uvrC protein and shown that it binds strongly to DNA. The third promoter, P3, located 341 base pairs before the structural gene, produces an in vitro transcript terminating in the region of lexA binding site. It is unclear whether P3 has a role in in vivo uvrB gene expression^{6A}. Identification of a second gene, himA, with dual control has recently been described by Miller et al. 12. The himA gene product is needed for site-specific recombination, best studied by integration of phage & DNA into the E. coli chromosome. λ integration accomplished by the combined action of λ int protein and host integration factor. himA's function is to encode one subunit of the host integration factor, the other subunit is probably specified by the himD gene. himA was found to resemble other genes in the SOS regulon in being induced by UV and mitomycin C provided the recA and lexA genes were functioning normally. However, himA and himD are also subject to an alternative control mechanism, since both genes are expressed at high levels when either one of their gene products is inactive. This indicates that himA and himD may jointly repress their own syntheses as well as forming host integration factor. Until the controlling regions of these genes have been sequenced, it is uncertain whether or not lexA, himA and himD proteins act at the same or different sites, and whether himD is also regulated by lexA.

Remarkably, the role of himA in lysogenization is not limited to providing a subunit of the host integration factor. Earlier work by Miller13 showed that humA

was also needed for efficient transcription from the λ promoters P_E and P_I , which direct synthesis of λ repressor and integrase. Miller suggested that himA possibly repressed the bacterial hfl gene whose product decreases activation of P_E and P₁ by \(\lambda \text{III}\) protein. Thus, \(\lambda \text{im} A\) also aids lysogenization by boosting synthesis of λ repressor and integrase. Int protein and host integration factor are also required for prophage excision during lysogenic induction, showing again how \(\lambda\) exploits

the SOS system to leave a host which might be dving.

The existence of at least two genes with dual regulatory mechanisms raises the possibility of a general scheme where many components of the SOS regulon may be capable of independent expression for 'routine' metabolism. Superimposition of a second SOS regulatory system would provide a means of coordinating diverse and unrelated metabolic pathways to aid cellular survival.

A Soviet view of the venusian surface

from Lionel Wilson

A highlight of this year's Lunar and Planetary Science Conference* was the session devoted to Venus, at the close of which Soviet scientists presented photographic panoramas and chemical analyses of the Venus surface obtained by the recent soft-landers Venera 13 and 14. The resolution of the new images is far better than those from earlier Soviet probes and the chemical data provide the first opportunity to make 'direct inferences about the internal geochemistry of Venus.

Studies of the Solar System over the last decade have shown that the other silicate planets - Mercury, Venus and Mars display a variety of surface features produced by processes identifiable on Earth; but no planet yet examined has a crust dominated by the kinds of largescale, plate tectonic processes which typify the Earth's outer layers. Until recently, however, the surface of Venus, the only planet truly comparable with the Earth in terms of size and mass, remained hidden beneath the dense, cloud-rich, CO₂ atmosphere. In 1975, the soft-landing Soviet spacecraft Veneras 9 and 10 provided low-resolution pictures of two parts of the surface, showing boulderstrewn terrains; but, although there was evidence of vesicular rocks1 these pictures only gave hints at the structures visible and the processes which might have formed

Attention switched to the large-scale structure of the crust of Venus when the US Pioneer Orbiter reached the planet late in 1978 and began to map the surface topography by radar. A consensus of opinion2 held that Earth-style plate tectonic processes were at best poorly developed on Venus and that heat was released from the interior at a series of localized mantle hotspots above which active volcanoes opinion, held that Earth-style plate tectonic crustal uplifts, the most prominent being the Beta Regio region. The Pioneer measurements, coupled with Earth-based radar data on surface roughness and dielectric constant, showed that the southern part of Beta Regio was one of the few areas where fresh, dense rocks, possibily recently erupted basaltic volcanics, were exposed at the surface.

Not all those studying Venus are reconciled to the absence of plate tectonic processes, however, and the debate continued at the Houston meeting. On the one hand, H. Spetzler and K.A. Goettel argued for a weak crust^{3,4} and J.L. Warner provided a mechanism⁵ for recycling the crust via the subsidence of interlavered volcanic rocks and aeolian sediments; in contrast, S. Solomon reviewed the reasons6 why we should not yet rule out any of the possible styles of tectonism proposed for Venus. In an attempt to sidestep the issue of tectonic regimes, L. Wilson and J.B. Garvin^{7,8} showed that, irrespective of magma chemistry, eruptions on Venus were likely to produce lava flows longer than those on Earth. Because of the high surface pressure on Venus (55-90 bars), explosive eruptions which produce dispersed ash layers could only occur if the volatile contents of erupting magmas were high by terrestrial standards, exceeding about three weight per cent.

The new Soviet results bear on all aspects of the topics outlined above. Highresolution images (showing millimetresized particles in the foreground) were obtained through red, green and blue filters at both landing sites and colour composites produced. In each case, the sky appeared to have a yellow hue while exposed rock surfaces were a yellowish orange and fine-grained materials showed a greenish tint. A drilling device obtained samples (thought to be mainly low-strength soils) from the vicinity of each lander and transferred them into an X-ray fluorimeter

system for major element chemical analysis (Table 1).

Table 1 Oxide analyses of Venus surface rock in weight per cent

Oxide	Venera	Venera
	13 site	14 site
SiO ₂	45	49
$Al_2\tilde{O}_3$	16	18
MgO	10	8
FeO	9	9
CaO	7	10
K ₂ O	4	0.2
TiO ₂	1.5	1.2
MnÕ	0.2	0.16

At the Venera 13 site, on rolling uplands high on the flanks of Beta Regio, extensive coherent strata are seen, together with isolated rocks showing some evidence of erosion. The composition of the rock sample is close to that typical of terrestrial

alkali basalts found in continental rift zones - a striking result when one recalls the proposed origin of Beta Regio as a rifted uplift over a hot-spot. Alkali basalts on Earth are associated with magma source regions rich in CO2 and the existence of such rocks on Venus lends support to the idea that CO₂-driven explosive volcanism may occur there despite the high surface pressure.

The surface at the Venera 14 landing site, in a lowland area south-east of Beta Regio. is dominated by extensive horizontal strata, 10-100 mm thick, which have the appearance of lithified sediments in the process of being eroded. The composition, however, is again very close to that of a terrestrial primary volcanic product, in this case an ocean-floor tholeiitic basalt. It is tempting to reconcile the composition with the sedimentary character of the rock by assuming that it is some kind of pyroclastic material, but then the problem of finding

sufficient volatiles to drive the eruption reappears. We should not jump to the conclusion that the tholeiitic nature of the Venera 14 rock necessarily implies that it was produced in a plate tectonic environment, as such a rock type would be on Earth. Indeed, too much must not be inferred about the interior of Venus from just two rock analyses; but it is ironic that each of the two analyses available, interpreted naively, supports one of the two main theories of Venus crustal structure.

Punctuationism and Darwinism reconciled?

The Lake Turkana mollusc sequence

On 8 October, 1981 P G Williamson1 presented an extraordinarily "complete page in the history of evolution" in a very detailed sequence of fossil molluscs from the the eastern Turkana basin in East Africa. All of 13 lineages, including ten which could be followed for 4-5 million years, showed a pattern of evolution conforming to the 'punctuated equilbrium' model: change was concentrated in short (5,000-50,000 years) speciation events, between long periods (3-5 million years) of morphological stasis. How is such a pattern to be

In the same issue, Jones² pointed out that the rapidity with which change occurred is certainly no greater than can be brought about by conventional Darwinian selection. The real problem, as Williamson3 and others4 have made clear, is to explain the very long periods of stasis. Williamson favours the view, originally put forward by Eldredge and Gould⁵, that stasis is primarily the result of "developmental constraint", which makes certain kinds of developmental change difficult or impossible, and that speciation must necessarily involve the dismantling of these mechanisms. He sees evidence of this process in the periods of extreme developmental instability (recorded as an increase in phenotypic variance) that accompany speciation events in his mollusc sequences.

A contrasting view is that stasis may be explained by stabilizing selection — that is selection favouring the typical members of a population rather than the extremes. If this explanation is correct, then as Maynard Smith points out in a new book (Evolution Now*) what we need is "a theory which says something about selection, and hence about the environment. Since the major component of the environment of most species consists of other species in the ecosystem, it follows that we need a theory of ecosystems in which the component species are evolving by natural selection."

Williamson's articles have stimulated a great deal of comment, a small part of which appears below. Questions are raised both as to the nature of the pattern recorded in the fossil lineages — whether or not the bursts of rapid change are truly genetic in origin — and its implications. The notion of developmental constraint is debated and more general points, such as whether the 'punctuated equilibrium' pattern could be brought about by varying rates of environmental change, or whether it could be an artefact of sampling time scales, are also examined.

Questions concerning speciation

from Ernst Mayr

THE pattern of evolution in the mollusc lineages reported by Williamson seems to be in excellent agreement with the theory of punctuated equilibria, which is based on the well-known paleontological observation that new species usually enter the fossil record abruptly (in geological time) and postulates that they persist subsequently with little significant change until extinction. The rapid change under the stress conditions of an evaporating Lake Turkana is, as Williamson points out, less of a puzzle than the millions of years of stasis.

Williamson refers to my observation that many currently living species show phenotypic uniformity even though their range extends over areas of considerable ecological and climatic diversity. This observation strengthens the thesis that it is not stabilizing selection of a set of essentially additive genes that is responsible for the stasis but rather the strength of the "internal balance" (Mather), "genetic homeostasis" (Lerner), "cohesion of the genotype" (Mayr). These authors postulate that the genotype as a whole is a finely balanced system, in which appropriate feedback mechanisms maintain morphological stability by compensating for whatever genetic changes occur through time at individual loci.

Williamson has presented a plausible explanation of his findings and it might well be the correct one. However, in his short communication, he has not refuted conceivable alternate theories nor has he provided answers to some disturbing questions that might arise in the mind of the reader.

First, Williamson states that the changes in 12 lines of sexually reproducing molluscs are paralleled exactly by events in the lineage of the asexually reproducing species Melanoides tuberculatus. Since an asexual phyletic lineage consists of hundreds, if not many thousands, of independent clones, how does Williamson explain that all of them experience a parallel history of equivalent genetic changes? This concordant phenotypic change of the scores of asexual clones suggests that the changes are not genetic at all, but merely modifications of the phenotype (see also the letter below from A.J. Boucot).

Second, does the variability of the asexual (*Melanoides*) lineage, consisting of numerous independent clones, differ from those of the sexual lineages?

Third, Williamson states that the new 'species' become suddenly extinct when the

Ernst Mayr is Alexander Agassiz Professor, Emeritus, in the Museum of Comparative Zoology, Harvard University, Cambridge, MA 02138

widespread parental species reinvade the Turkana basin. There are four sets of possibilities for the behaviour of parental and daughter "species" at the time of the establishment of sympatry: (a) Conditions in the Turkana basin, before the reinvasion by the widespread parental stocks, had deteriorated to such an extent that the new "species" had all become extinct already; (b) They had become reproductively isolated; in that case it should be possible to find them sympatrically in zones of contact: (c) They had not yet developed reproductive isolation and it should be possible to find hybrid populations with greatly increased variability; (d) The observed morphological differences of mother and daughter 'species' had no genetic basis but were merely phenotypic responses to different environmental conditions; in that case a sudden and total change of the phenotype should accompany the replacement of the lake waters. A finegrained analysis of the populations occurring during the crucial period of reversion to standard conditions should permit an answer to these questions.

Finally, one would also like to know more about one set of puzzling speciations. In six of the 13 lineages a second species

apparently originated in the lower Koobi Fora Formation (Bellomya unicolor, Cleopatra ferruginea, Melanoides tuberculatus, Caelatura bakeri, Mutela nilotica, and Eupera ferruginea). All six of these daughter species seem to become extinct before the end of the lower Koobi Fora (see Fig. 4). Do these six new daughter species coexist sympatrically with the parent stock without producing intermediates? Does Williamson believe that they originated in some peripheral isolate (a temporarily isolated lagoon?) and were able, after a rise in lake level, to invade the range of the parent stock? Several other questions are obvious, but one can not even begin to answer them until Williamson produces more factual evidence about these six postulated speciation events.

Williamson states that, on the whole, his findings are consistent with my theory of peripatric speciation in peripheral founder populations, with two drastic exceptions: The asexual Melanoides behaves like the sexual lineages, a fact not explained by Mayr's postulate of genetic revolutions, and the size of the shell deposits indicates that the 13 (19) lineages never truly seem to have passed through a narrow populational bottleneck, as demanded by the theory of peripatric speciation. It is impossible to resolve this conflict -Williamson himself does not try to do it until much better factual evidence for some of the events in the sequence of these mollusc faunas is presented.

Ecophenotypic or genotypic?

from Arthur J. Boucot

WILLIAMSON's brief comment (p. 441) that the presumably derivative morphologies, all arrayed in two, well-dated, very discrete horizons and one more diffuse horizon, cannot be considered to be ecophenotypic morphologies of the unchanging, longranging forms - many of which persist to the present — needs discussion. It is essential that in an area where lake waters of widely different composition are known to have occurred in the past, as well as the present, that the possibility of ecophenotypic, as contrasted with a genetic, change be dismissed only when adequate data has accumulated. One would have hoped that Williamson would have provided us with observational data, based on those species that persist to the present, showing that under conditions of varied lake water composition (both concentration and composition) there are no ecophenotypic effects.

If such data are unavailable, Williamson could have cultured at least some of the living species under conditions of salinity and water composition that might have

occurred in parts of the Turkana Basin region during the time interval studied. Without such data one must be forgiven for still considering that the possibility of ecophenotypic change is fully as rational as that of speciation. Few neontologists would adhere to the tenet that distinctly different skeletal morphologies within a genus invariably indicate different genotypes. Paleontologists normally assign distinctly different morphologies within a genus to different species, lacking evidence for a well documented morphologic gradient of ecophenotypic type, only because they commonly deal with extinct genera; not because they feel that the procedure is invariably defensible.

Finally, Williamson really should have provided us with a satisfying explanation of why speciational events should have occurred simultaneously, at two distinct

Arthur J. Boucot is in the Department of Geology, Oregon State University, Corvallis, Oregon 97311.

and one diffuse horizon, within a variety of unrelated molluscs. This certainly is a strange coincidence from an evolutionary point of view, although entirely plausible from the ecophenotypic point of view if a major change in lake water chemistry and concentration affecting an arm of a large

lake was involved. The long stratigraphic range of those stocks still represented today makes it clear that they were present in the region throughout the entire time interval, whereas all of the morphologies derived from them during the brief intervals of morphologic change

lasted a very short time — this situation is entirely consistent with either local speciation under unknown physical conditions, or under locally isolated conditions involving different enough conditions to produce distinctive ecophenotypes.

Morphological stasis and developmental constraint: no problem for Neo-Darwinism

from Brian Charlesworth and Russell Lande

THE critical issue stemming from Williamson's papers is the explanation of stasis and increased variability associated with the episodes of change. The view he holds, that stasis is due to developmental constraints2, is equivalent to saying that the characters concerned lack genetic variability, so that selection is ineffective. But there is evidence for substantial levels. of heritable variability in most morphological characters that have been studied1,4, including snail shell traits5,6.

Stasis cannot, therefore, be explained by developmental constraints; either the characters are selectively neutral and population sizes are too large for genetic drift to be effective, or natural selection acts towards an intermediate optimum phenotype. Direct evidence for such stabilising selection on shell characters in snails was provided by the early biometricians^{7,8}, and similar data is available from many other traits9. Williamson is also incorrect in implying that stabilising selection has only recently been invoked by neo-Darwinists as an explanation of stasis; for example, Simpson (ref. 10, pp148-150 and 327-355) discusses this question at length.

The observation of increased variability

Brian Charlesworth is in the School of Biological Sciences University of Sussex, Falmer, Brighton BNI 9QG and Russell Lande in the Department of Biophysics and Theoretical Biology, The University of Chicago, Chicago, Illinois 60637.

at times of rapid change could have several explanations not discussed by Williamson. He neglects the possibility that it could be caused by a direct developmental response to increased heterogeneity of the habitat, or by the effects of temporal fluctuations during individual lifetimes, at periods when the environment is changing. Furthermore, since fossils classed as belonging to one geological horizon almost certainly span many generations, rapid evolutionary change over the period of sampling could generate increased variation. For these reasons, we are not convinced that the increased variation is a genuine evolutionary phenomenon. But even if this is granted, there would be no difficulty for neo-Darwinism. Selection experiments have demonstrated that stabilising selection can enhance developmental stability, or zones of

'canalisation', around an optimum phenotype by altering the patterns of genetic and non-genetic variation¹¹⁻¹³. Relaxation of stabilising selection14, and/or directional selection away from a zone of canalisation15-17, would then be predicted to produce an increase in phenotypic variability, until the population is recanalised by stabilising selection around a new optimum phenotype¹⁸ (Kirkpatrick, Am. Nat., in press). However, many characters under weak stabilising natural selection are not canalised in their appreciably development, and can be artificially selected to change a great deal without substantially increasing their variability4. The exact temporal patterns of variability expected thus depend on factors whose relative weights are difficult to assess for fossil material.

Are 'punctuations' artefacts of time-scales?

from Lev R. Ginzburg and Jay D. Rost

WE would like to give a brief explanation of why the 'punctuated' pattern of evolutionary change seen in Williamson's and other, less well documented, findings may well be an artefact of the sampling time scales. A more detailed argument is presented elsewhere¹.

Consider the following imaginary example: A population of E. coli is cultivated in a chemostat under a fixed environment for a number of years. Assume that we sample cells from the culture with different time intervals to discover whether the culture has evolved or not with respect to a quantitative trait. If we do this, biweekly, for instance; we will find most of the time that nothing has happened. Occasionally will we find changes that appear as punctuational, since the replacement time in a chemostat is typically much shorter than two weeks. Now, if we make our observations hourly, the details of the replacement process will be obvious and the evolutionary change will appear gradual. If we make only yearly observations, the process may look gradual for a different reason; we would average a number of changes during the year into one vearly change.

If we repeat the experiment with a number of isolated chemostats, and carry out bi-weekly sampling for a period of a few months, we expect most of the populations to show no change, but some of them will evolve away from the majority. This may look like a punctuative "speciation event." Too fine or too coarse a time scale will always lead to a more "gradual" picture, whereas at some intermediate scale, the process will appear as "punctuational." In the work of Williamson the mean time scale resolution is between 30,000 and 35,000 years. (The value is the sum of the time spans of segments 2, 3, 4 and 5, about 2.5 Myr,

divided by 79 sample points). If a typical replacement time is significantly less (selective advantages of $10^{-4}-10^{-5}$ per year), our hypothesis may well be correct. Note that other well-documented studies claiming support for gradualism appear to have scale resolutions significantly greater than this. These researchers may be sampling at too coarse a time scale to detect 'punctuational' events (See Table below).

Punctuated equilibria and punctuated environments

from D.W. Lindsay

EVOLUTION is not an event which occurs without external agency. A selective pressure is necessary for evolution to occur and must be an important determinant of the rate of evolution. Where such rates appear to vary, as Williamson's study shows, surely the first aspect of the problem to receive attention should be the selective pressures involved. In a stable lacustrine environment, as seems to have existed between the bouts of 'speciation' described by Williamson, selective pressures may have been low or minimal so that a lack of change in a few correlated characters seems rather unsurprising. Equally unsurprising are sudden series of changes coinciding with 'major lacustrine regressions'. These would clearly introduce marked selective pressures and a consequent flurry of genotypic and phenotypic experimentation until adaptation had been attained, or not,

D.W. Lindsay, 10, Wordsworth Avenue, Maldon, Essex CM9 6BZ

and the environment stabilised. Thus, observations of stasis interspersed with rapid change may simply reflect changes in the direction and intensity of the selective pressures which are implied by the stratigraphic record. Generally, we ought to consider a punctuated environment in thoughts on punctuated environment in thoughts on punctuated evolution. It is a sad fact of paleontology that the conditions of stable, prolonged sedimentation which favour preservation may lead to low rates of evolution, while periods of environmental hiatus which would have accelerated the process may often be lost in the unconformities.

Williamson replies:

In answer to Mayr's first point: It is surely unneccessary to postulate that all the clones of Melanoides present in the Turkana Basin underwent parallel genetic changes during the episodes of morphological transformation at the Suregei and Guomde levels. It seems more probable that one, or a few, such clones made an appropriate evolutionary response to the relevant selective pressures, and that, as these few clones evolved, they proceeded to outcompete other 'conspecific' clones. Such interclonal competition is well documented, and Mayr himself has suggested competitive elimination of inferior clones as the probable mechanism whereby discontinuities between closely related asexual 'species' arise2. I address Mayr's further suggestion (that the transformations morphological documented in the Turkana sequence are purely ecophenotypic reactions) below.

In response to Mayr's second point: The variability (c.v.) of all measured traits in populations of the asexual taxon *Melanoides tuberculata* are quite comparable to the variabilities documented in typical populations of the gonochoristic gastropod taxa³.

Mayr's third point: The details surrounding the sudden reinvasion of parental stocks into the basin above the Suregei Tuff level speciation event, synchronous with a major lacustrine transgression, are at present poorly understood. Some 2-3 metres of fossilbarren sediment separates the last of the novel Suregei level forms from the first of the returning ancestral stocks. No hybrids, sympatric faunas or intermediates are currently known. It is not therefore possible to distinguish between Mayr's options (a), (b) and (c). But as discussed below, Mayr's option (d) appears untenable.

Mayr is correct in noting a set of speciation events in certain lineages in the Lower Member of the Koobi Fora Forma-

tion. These new forms appear suddenly in the record and coexist with their ancestral stocks; the event is therefore a modest adaptive radiation typical of that seen in many modern rift lakes. All these new endemics become extinct by the top of the Lower Member, due to a climatically induced regression — and consequent increase in alkalinity — well documented in the uppermost part of the Lower Member. It is indeed likely, that these new endemics arose in peripheral isolates of the large Lower Member lake, perhaps in the manner suggested by Hubendick⁴.

With reference to Mayr's last paragraph: I believe that it is indeed possible to resolve the conflict between Mayr's model of peripatric speciation and my observations in the Turkana Basin. I hope to address this topic in a forthcoming paper.

Boucot — and also Mayr — suggest that the novel forms I document as arising at the Suregei, Guomde, and Lower Member levels may simply be ecophenotypic 'reactive forms' of the 'ancestral' lineages. Several factors strongly indicate that this is not the case: (1) the novel forms arising in the Lower Member coexist with their presumed ancestral forms, and occur with them in the same 'life-assemblages'. The Lower Member novelties at least can not be simple ecophenotypic variants⁵. (2) The principle stem lineages in the Turkana Basin sequence are still extant and widely distributed in Africa, but even the most extreme modern environments in which these lineages occur at present produce a simple dwarfing of characteristic morphology (or in extremis, extinction of local populations), they never produce the striking reorganization of phenotype documented in the Turkana Basin sequence⁵. (3) The morphological transformations documented at the Suregei Tuff level are invariably unidirectional in character space, and required some 103-104 generations to accomplish6. This is hardly the nature or time-scale of a conventional ecophenotypic response⁵ The magnitude of phenotypic change during the Suregei and Guomde Level episodes is striking. In the bivalves, these changes involve a radical restructuring of shell form and hinge dentition, and major changes in the disposition of the muscle scars. The magnitude of the changes documented in both bivalves and gastropods is generally far greater than that observed in the ecophenotypic transformations of even the most plastic of modern African freshwater molluscs³. I do not therefore believe that the profound morphological transformations documented in the Turkana Basin sequence can be simply 'written off' as an ecophenotypic response.

Boucot expresses surprise that all lineages at the Suregei and Guomde levels speciate. But it has long been acknowledged that two major 'triggers' for speciation events within peripheral isolates are (1) isolation per se and (2)

environmental stress7. The Suregei and Guomde Level speciation events occur at times of lacustrine regression. The various molluscan lineages have similar vagilities, and occupy similar environments. All would therefore experience both isolation and stress during a major regressive phase. A broadly synchronous evolutionary response in all lineages is therefore reasonable.

Charlesworth and Lande are incorrect in assuming that evidence for substantial heritable variability in morphological characters implies that morphological stasis cannot be attributed primarily to developmental constraint. The question is not so much whether variation exists for selection to work on, but rather what, if anything, selection can actually make of this variation in nature. Developmental constraint may well block long-term directional morphological trends in large populations, even though the genetic potential for such evolutionary transformation exists. This is at least one tenable explanation for the fact that, in the record, such long-term morphological trends are rare, or absent, in continuous phyletic sequences.

Morphological stasis is not, therefore, a reflection of selective neutrality of phenotypes or simple stabilizing selection. The idea that most phenotypes are selectively neutral is not widely held, nor supported by Charlesworth and Lande's own references8. Neither is simple stabilizing selection an adequate explanation for long term morphological stasis. Many species - perhaps most exhibit stasis for millions of years. The idea that such species experience an unchanged selection regime for these immense spans of geological time seems inherently unlikely. Conventional neo-Darwinists have similarly recognised that simple stabilizing selection is an inadequate explanation for the analagous situation of range-wide phenotypic coherence in modern species; they therefore invoke developmental constraints of one form or another to explain this coherence9. In asserting such constraints to be the principal element in long-term temporal stasis, punctuationists are following the lead of conventional neo-Darwinian students of geographic variation.

Certain neo-Darwinists have recognised the primacy of developmental constraint in maintaining evolutionary stasis. For example Rendel¹⁰ states that "when a canalised character is to be changed the unfitness introduced when the fine adjustment between developmental processes is destroyed will always be counteracting directional selection . . . directional selection must always introduce unfitness. This antagonism between fitness and directional selection will have to be taken into account in interpreting long [term] stability. . .'

Charlesworth and Lande suggest that the greatly enhanced phenotypic variability I

document during periods of morphological transformation in the Turkana sequence simply represents a direct developmental response to increased heterogeneity of the environment. No evidence of any similar response is known from any modern population of the lineages concerned, even in the extremely wide range of environments many of them currently occupy; it hardly seems necessary to invoke them in this case. They then suggest that this variability might be due to 'mixing' of more- or -less evolved and stratigraphically adjacent populations. But as I point out5, the faunal units concerned seem to be undisturbed life assemblages with no evidence of reworking, and much of the variability derives from the presence of phenodeviants bearing as little relationship to the derived species as they do to the ancestral form. This does not suggest that the increased variability I document is due to the mixing of the products of a conventional neo-Darwinist evolutionary 'march of means'. It suggests pronounced developmental instability in the transitional forms. Charlesworth and Lande finally concede that this increased variability may represent developmental instability resulting from strong directional selection away from a zone of canalization - which is, after all, the explanation I offered in my original paper.

Ginzburg and Rost are correct in considering the gradualist and punctuational models to be, in part at least, alternate hypothesis about the distribution of rates of evolutionary change. But the critical issue in this context is the extent to which observed rates of change in a given interval can be extrapolated up into rates of change occurring in any longer time interval.

If Ginzburg and Rost's bacteria were evolving according to the gradualist model, the amount of change observed over any given sample interval could be extrapolated up to account for the net change occurring over any larger sample interval. If the bacteria were evolving according to the punctuational model, the amount of change observed over any given sample interval could not be extrapolated up into the net amount of change observed over a much larger interval. In the latter case, if a given sample interval happened to include a 'speciation event', estimated rates of net change over a larger sample interval would be much too high (long periods of stasis would occupy most of a longer time period). If, more likely, one happened to sample a period of stasis, extrapolated rates of change for a larger sample interval would be much too low, that is effectively zero.

The sampling time scale is therefore irrelevant to the punctuationist-gradualist controversy. In any case, much more than simple differences in rate of evolutionary

100 YEARS AGO

On Tuesday evening, April 11, the public thoroughfare stretching between Hatton Garden and the Old Bailey was lighted for the first time by the electric light. The novelty of the installation was the fact that the incandescent system had been adopted in preference to the arc system. The Holborn street lamps each contain two of Edison's bulbs suspended from a cross bar running through the top of the lantern. The light is of a golden tinge like gas, but much purer, brighter, and steadier. The lamps were switched on and off with the greatest ease, and altogether the experiment was a complete success.

Mount Etna has again been in an active condition. An eruption and a rain of ashes (rampilli) has quite recently alarmed the neighbouring inhabitants.

from Nature 25, 564-5; April 13, 1882.

change are involved in the differences between the punctuated and gradualist models: for example, the size of the populations in which significant evolutionary changes is thought to occur is also a critical distinction between these two models11.

Lindsay suggests that selection pressure is a sine qua non of evolutionary change. He ignores such staples of conventional neo-Darwinism as founder effect, genetic drift, mutation pressure and the appearance of 'super fecund' mutants, all of which phenomena are thought to effect evolutionary change irrespective of — or even in opposition to — selection pressure. But Lindsay ignores these, and suggests that the 'variation in rates' I observe in the Turkana section are the simple consequence of variations in the Suregei and Guomde Level although speciation events occupy only $5 \times 10^3 - 5 \times 10^4$ yrs represented by the Turkana sequence. In other words, according to Lindsay, for only 1 per cent or 0.1 per cent of the time represented by the Turkana Basin sequence were selection pressures adequate to elicit any evolutionary response in any lineage. For the remaining 99 per cent or 99.9 per cent of the time, selection pressures were 'so low or minimal' - for 5 Myr - that no significant change occurred whatsoever in any lineage. Lindsay describes this as unsurprising. I find it incredible! In fact, even the most conventional of neo-Darwinists would agree that rates of evolutionary change are controlled by many more factors than simple fluctuation in selection pressures.

REVIEW ARTICLE

The role of protein phosphorylation in neural and hormonal control of cellular activity

Philip Cohen

Department of Biochemistry, University of Dundee, Dundee DD1 4HN, UK

Protein phosphorylation is now recognized to be the major general mechanism by which intracellular events in mammalian tissues are controlled by external physiological stimuli. However, only recently has the idea that different cellular functions are controlled by common protein kinases and protein phosphatases started to gain widespread acceptance. Thus there is an integrated network of regulatory pathways, mediated by phosphorylation—dephosphorylation, that allows diverse cellular events to be coordinated by neural and hormonal stimuli. The evidence that supports this concept is reviewed, with emphasis on the role of protein phosphorylation in enzyme regulation.

THE presence of phosphorus in proteins has been known for almost 100 years, but its importance has only been realized since the discovery of enzyme regulation by reversible phosphorylation. The current excitement stems from the work of Krebs, Fischer and Larner over the period 1955–70, when they discovered that the neural and hormonal control of glycogen metabolism in skeletal muscle was mediated by changes in the phosphorylation state of glycogen phosphorylase¹, phosphorylase kinase² and glycogen synthase³ (Fig. 1).

These three enzymes remained the only examples of this phenomenon until the late 1960s, but the situation changed rapidly following the discovery of cyclic AMP-dependent protein kinase (cAMP-PrK)⁴. The past 10 years have seen an extraordinary and still accelerating growth in this area. About 35 enzymes and countless other proteins are now known to be regulated in this manner, and protein phosphorylation is clearly the major general mechanism by which intracellular events respond to external physiological stimuli⁵.

The first part of this review will summarize current knowledge of the control of glycogen metabolism, as this system is understood in the greatest molecular detail and continues to act as a model with which others are compared. The second part will present the increasing body of evidence that implicates many of the proteins involved in the control of glycogen metabolism in the regulation of other cellular activities.

Neural and hormonal control of glycogen metabolism in mammalian skeletal muscle

Glycogen is a major source of energy for muscle contraction. Its breakdown and synthesis are regulated by the contractile state of the tissue as well as by the hormones adrenaline and insulin, through changes in the phosphorylation state of glycogen phosphorylase and glycogen synthase (Fig. 1). These interconversion reactions are now known to involve five different protein kinases, four protein phosphatases, and regulatory proteins such as calmodulin, troponin-C, inhibitor-1 and inhibitor-2. Some of these proteins allow glycogen metabolism to respond to the second messengers Ca²⁺ and cyclic AMP (Fig. 1). The role of other proteins is less clear, although they may be involved in the action of insulin. Recent advances in understanding the molecular mechanisms underlying these reactions are summarized below.

Neural control via calcium ions: When muscle is stimulated electrically, calcium ions released from the sarcoplasmic

reticulum not only initiate muscle contraction but also activate phosphorylase kinase^{6,7}. As a result, the phosphorylation state of glycogen phosphorylase is increased⁸⁻¹⁰ and glycogenolysis is accelerated to provide the ATP required to sustain muscle contraction. Recently, phosphorylase kinase has been shown to phosphorylate glycogen synthase and to decrease its activity¹¹⁻¹⁵. Thus, the two opposing pathways of glycogenolysis and glycogen synthesis may be regulated in a synchronous manner during contraction.

Phosphorylase kinase is the key to both the neural and hormonal mechanisms for stimulating glycogenolysis, as it is not only dependent on Ca^{2+} , but is also a target for cAMP-PrK (Fig. 1). The enzyme has the subunit structure $(\alpha\beta\gamma\delta)_4$, where the α - and β -subunits are the components phosphorylated by cAMP-PrK 16,17 , the γ -subunit seems to be the catalytic subunit 18 and the δ -subunit is the Ca^{2+} -binding subunit 19,20 . The δ -subunit is identical to calmodulin $^{19-22}$, a protein

The δ -subunit is identical to calmodulin ¹⁹⁻²², a protein originally discovered as an activator of a quite different enzyme but which is now implicated in the regulation of many Ca²⁺-dependent enzymes (discussed below). Calmodulin binds four calcium ions per mol at micromolar concentrations²³, the affinity of the two Ca²⁺-binding sites in the N-terminal portion being 10-fold higher than those in the C-terminal domain²⁴.

Phosphorylation by cAMP-PrK activates phosphorylase kinase \sim 15-20-fold at saturating Ca²⁺ concentrations and decreases the K_a for Ca²⁺ \sim 15-fold²⁵. Thus, phosphorylation not only enhances the activity of the γ -subunit, but may also allow activation to occur when fewer calcium ions are bound to calmodulin. This suggests a biological role for the different classes of Ca²⁺-binding sites in calmodulin²⁶.

Phosphorylase kinase has been found to interact with a second molecule of calmodulin, termed the δ' -subunit, which only binds to the enzyme in the presence of Ca^{2+} where it interacts with the α - and β -subunits. In contrast, the integral molecule of calmodulin (the δ -subunit) remains complexed with the γ -subunit even in the absence of Ca^{2+} (refs 20, 27, 28). The δ' -subunit strongly activates the dephosphorylated form of phosphorylase kinase but has little or no effect on the phosphorylated form²⁵.

Calmodulin is closely related in structure and Ca^{2+} -binding properties to troponin- C^{22} , the protein on the thin filaments of muscle that confers Ca^{2+} sensitivity to the contractile apparatus. Troponin-C, the troponin complex, and even artificial thin filaments of muscle, can substitute for the δ' -subunit, and several lines of evidence suggest that troponin-C rather than

Table 1 Classification of protein phosphatases in cellular regulation

Туре	Protein phosphatase	Inhibited by I ₁ and I ₂	Specificity for phosphorylase kinase	Substrate specificity	Regulators
1	Protein phosphatase-1	Yes	β-subunit	Broad	$I_1, I_2, GSK-3+Mg^{2+}-ATP$
2	Protein phosphatase-2A	No	α-subunit	Broad	Unknown
2	Protein phosphatase-2B	No	α -subunit	Narrow	Ca ²⁺ calmodulin
2	Protein phosphatase-2C	No	α -subunit	Broad	Mg ²⁺

Protein phosphatases-2B and -2C are completely dependent on Ca^{2+} and Mg^{2+} , respectively, whereas protein phosphatases-1 and -2A are active in the absence of divalent cations. Protein phosphatases-1 and -2A have very similar substrate specificities. The specificity of protein phosphatase-2C is also broad, although it does not act on some phosphoproteins such as phosphorylase a (refs 52-55). Protein phosphatase-2B has a very restricted specificity, and of many phosphoproteins examined, only phosphorylase kinase (α -subunit), inhibitor-1 and myosin light chains have so far been found to serve as substrates^{69,70}. Abbreviations: I_1 , I_2 , inhibitor-1 and inhibitor-2; GSK-3, glycogen synthase kinase-3.

the δ' -subunit may be the important activator in $vivo^{25,26}$. At physiological Ca²⁺ concentrations (1–3 μ M), the dephosphorylated form of phosphorylase kinase is activated ~20-fold by the troponin complex^{25,26}.

Figure 2 summarizes current ideas about the regulation of glycogen metabolism by Ca^{2+} . Phosphorylase kinase is controlled by two related Ca^{2+} -binding proteins, but their relative importance depends on the phosphorylation state of the enzyme. Troponin-C seems to be the dominant regulator of the dephosphorylated form, while calmodulin (the δ -subunit) determines the Ca^{2+} sensitivity of the phosphorylated species. Activation of glycogenolysis and muscle contraction by the same Ca^{2+} -binding protein (troponin-C) represents a simple mechanism for synchronizing these two processes, and perhaps this is why phosphorylase kinase is so large (molecular weight 1,300,000 ref. 17)), having to span the distance between the protein–glycogen complex and thin filaments if these ideas are correct. Knowledge of its precise intracellular location in contracting muscle will be required to test this hypothesis.

Hormonal control of glycogen metabolism by multi-site phosphorylation: It was perhaps fortunate that the first example of enzyme regulation by reversible phosphorylation (activation of glycogen phosphorylase by phosphorylase kinase) should involve phosphorylation at a single site by a single protein kinase, since it greatly facilitated elucidation of the complex

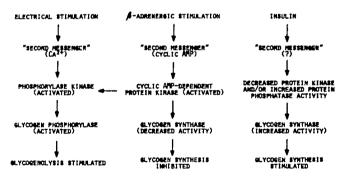

Fig. 1 Knowledge of the neural and hormonal control of glycogen metabolism in mammalian skeletal muscle up to 1970.

effects of covalent modification on the kinetic properties²⁹⁻³². This situation is relatively uncommon, however, and 'multi-site phosphorylation' is turning out to be the rule rather than the exception.

Phosphorylase kinase is phosphorylated on two serine residues by cAMP-PrK at physiological Mg^{2+} concentrations, one on the α -subunit and one on the β -subunit 16,17 . Both serine residues become phosphorylated in vivo in response to adrenaline Phosphorylation of the β -subunit occurs most rapidly in vitro, and activation correlates with the extent of phosphorylation of this subunit 17,33,34 . Phosphorylation of the α -subunit does not alter the activity 34,35 and its function is unclear. It was initially thought that phosphorylation of the α -subunit stimulated the rate at which the β -subunit was dephosphorylated 34,35 ,

but the experimental observations on which this hypothesis was based can now be explained by a quite different phenomenon³⁷.

Glycogen synthase is phosphorylated on seven serine residues by five different protein kinases, and all seven sites are phosphorylated *in vivo*. Cyclic AMP-dependent protein kinase phosphorylates sites 1a, 1b and 2 (ref. 38), phosphorylase kinase site 2 (ref. 12), glycogen synthase kinase-3 sites 3a, 3b and 3c (ref. 39), glycogen synthase kinase-4 site 2 and glycogen synthase kinase-5 site 5 (ref. 40). The organization of the sites in the polypeptide chain⁴¹ is shown in Fig. 3.

The effect of phosphorylation is to decrease the activity of glycogen synthase, although the changes in kinetic parameters are complex, and different phosphorylation sites have different effects. Phosphorylation increases the $K_{\rm m}$ for the substrate UDP-glucose, decreases the $K_{\rm l}$ for inhibitors such as inorganic phosphate and ADP, and increases the $K_{\rm l}$ for the activator glucose 6-phosphate⁴². Phosphorylation of sites (3a+3b+3c) influences the kinetic parameters to a greater extent than does phosphorylation of site 2 or site 1a, but the effects are additive so that even larger changes are produced when all five sites are phosphorylated^{40,43}. The phosphorylation of site 1b or site 5 does not seem to affect the kinetic properties^{38,40}.

In normally fed animals, glycogen synthase contains 3 mols of phosphate bound covalently to each subunit, with the phosphorylation of sites (3a+3b+3c) having a dominant role in determining the kinetic properties⁴⁴. Following the administration of adrenaline there are 5 mols of phosphate on each subunit of glycogen synthase⁴⁴⁻⁴⁶, and the activity of the enzyme is decreased mainly by increased phosphorylation at site 2 and sites $(3a+3b+3c)^{44}$.

The finding that site 2 becomes fully phosphorylated in response to adrenaline in conditions where site 1a phosphorylation is only increased slightly was unexpected, as site 1a is phosphorylated much more rapidly than site 2 by cAMP-PrK in vitro, and is dephosphorylated more slowly³⁸. The increased phosphorylation of site 2 may therefore be mediated indirectly by cAMP-PrK, through the activation of phosphorylase kinase (Fig. 3). Even more surprising was the finding that almost half of the increase in phosphate occurs at sites (3a+3b+3c), which are phosphorylated by glycogen synthase kinase-3. This enzyme is unaffected by cyclic AMP⁴³ and does not seem to be a substrate for cAMP-PrK (B. A. Hemmings and P. Cohen, unpublished work).

Recent studies indicate that the activation of glycogen synthase by insulin is largely explained by decreased phosphorylation of sites (3a+3b+3c) (P. J. Parker and P. Cohen, unpublished work). These results suggest that glycogen synthase kinase-3 may be controlled by insulin, which is particularly interesting in view of the surprising discovery that this protein kinase is also an activator of protein phosphatase-1, the major glycogen synthase phosphatase in skeletal muscle (see the following section).

Multi-site phosphorylation is a simple mechanism for greatly increasing the regulatory potential of enzymes and is being found to be a common occurrence. Phosphorylation at one site may amplify or even antagonize the effects of phosphorylation at other sites, or alter the rates at which they are phosphorylated

or dephosphorylated. The mitochondrial pyruvate dehydrogenase complex⁴⁷⁻⁴⁹ and retinal membrane protein rhodopsin^{50,51} are well established examples of this phenomenon. The phosphorylation of three serine residues on the α -subunit of pyruvate dehydrogenase may help to lock this enzyme into the inactive state in conditions such as insulin deprivation, thereby preventing the oxidation of glucose or its conversion to fatty acids. The phosphorylation of five serine and threonine residues at the C-terminus of rhodopsin may be involved in the regulation of dark-light adaptation. Phosphorylation at different sites by different protein kinases enables enzymes to respond to several physiological stimuli, and in such situations interactions between phosphorylation sites may frequently represent the mechanism by which one stimulus influences another. A number of examples which illustrate this idea will be described below. Protein phosphatases involved in glycogen metabolism in skeletal muscle: Four distinct enzymes, termed protein phosphatase-1 and protein phosphatases-2A, -2B and -2C (Table 1), have been identified in mammalian skeletal muscle and other tissues that are capable of dephosphorylating the enzymes of glycogen metabolism⁵²⁻⁵⁵. Protein phosphatase-1 specifically dephosphorylates the β -subunit of phosphorylase kinase and is powerfully inhibited by two proteins termed inhibitor-1 and inhibitor-2 (see below), whereas the three type-2 protein phos-

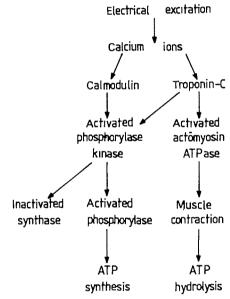

Fig. 2 Role of Ca²⁺, calmodulin and troponin in synchronizing glycogen breakdown, glycogen synthesis and muscle contraction.

phatases preferentially dephosphorylate the α -subunit of phosphorylase kinase and are unaffected by these inhibitor proteins. The concentrations of protein phosphatases-2A and -2C are low in skeletal muscle, and account for only a small proportion of the phosphatase activity towards the enzymes of glycogen metabolism in this tissue. These two enzymes are present at higher concentrations in the liver, and are likely to be more important in the regulation of other metabolic pathways (see below).

Protein phosphatase-1 is the most important enzyme in the regulation of glycogen metabolism in skeletal muscle³⁶, where it is the major phosphatase for glycogen synthase, glycogen phosphorylase and the β -subunit of phosphorylase kinase. A single enzyme therefore carries out each of the dephosphorylation reactions that inhibit glycogenolysis or activate glycogen synthesis (Fig. 4). It is becoming increasingly clear that protein phosphatase-1 is controlled in a variety of ways. A form of the enzyme has been isolated that is completely inactive until incubated with a further protein and Mg²⁺-ATP^{37,56-61}, and this activating protein has surprisingly turned out to be glycogen synthase kinase-3^{59,60}. Although there is not yet any evidence

that this activation system operates in vivo, an attractive idea is that it might be under the control of insulin⁵.

A further mechanism by which protein phosphatase-1 is regulated is through its interaction with the two thermostable proteins inhibitor-1 and inhibitor-2^{36,62-65}. It is of special interest that, only after phosphorylation on a threonine residue by cAMP-PrK^{56,60-62,65-68} can inhibitor-1 inhibit protein phosphatase-1 (Fig. 4). By such means inhibitor-1 provides a mechanism for amplifying the effects of cyclic AMP and for exerting control over several protein kinase-protein phosphatase cycles. Inhibitor-1 may also allow cyclic AMP to control enzymes that are phosphorylated by protein kinases other than cAMP-PrK. This would be the simplest explanation for the increased phosphorylation of glycogen synthase at sites (3a + 3b+3c) in response to adrenaline, and may also contribute to some of the increased phosphorylation at site 2.

Interestingly, inhibitor-1 does not inhibit its own dephosphorylation by protein phosphatase-1⁶⁴; consequently, protein phosphatase-1 could dephosphorylate inhibitor-1 in vivo. However, protein phosphatases 2A and 2B are also powerful inhibitor-1 phosphatases in vitro. It has recently been discovered that protein phosphatase-2B is a Ca²⁺-dependent enzyme that is stimulated 10-20-fold by calmodulin^{69,70}, suggesting that it may only be active during muscle contraction. The dephosphorylation of inhibitor-1 by protein phosphatase-2B, if it occurred in vivo, might therefore represent a mechanism for the activation of protein phosphatase-1 during contraction. This should stimulate the rate at which glycogen is resynthesized when contraction ceases, and allow the rate of glycogen synthesis in resting muscle to be linked to the strength and duration of the previous contraction.

Role of regulatory proteins of glycogen metabolism in other cellular processes

Cyclic AMP-dependent protein kinase: Although originally discovered as an activator of phosphorylase kinase⁴, it soon became obvious that cAMP-PrK must have a much wider role in mediating the diverse effects of cyclic AMP. The hypothesis arose⁷¹ that the specificity of a hormone is determined by whether its receptor is present on the plasma membrane of a

target cell, and which physiological substrates for cAMP-PrK are present within those cells. In the case of substrates that are enzymes, the effect of phosphorylation is often to change the $K_{\rm m}$ for a substrate, the $K_{\rm a}$ for an activator or the $K_{\rm l}$ for an inhibitor, as clearly illustrated by the enzymes of glycogen metabolism. Substrates, activators and inhibitors may also affect the rate at which an enzyme is phosphorylated or dephosphorylated, thereby amplifying or suppressing the effects of covalent modification. Phosphorylation—dephosphorylation should not therefore be regarded as a mechanism for turning an enzyme

5

on or off but rather for switching it between two forms (or up to several hundred in the case of enzymes with complex subunit structures that exhibit multi-site phosphorylation) that respond differently to substrates and regulator molecules. The interplay between covalent phosphorylation, allosteric effector molecules and substrates represents the means by which extracellular (neural and hormonal) and intracellular information is integrated to determine the precise activity of a metabolic pathway in vivo.

One obvious prediction of this model is that many substrates for cAMP-PrK must exist in different cells to explain the great diversity of action of many hormones, and it has become increasingly clear that this is the case. A number of enzymes are regulated by cAMP-PrK in vitro and are likely to be physiological substrates for this enzyme. The activation of triglyceride lipase⁷² and inactivation of glycerol phosphate acyl transferase⁷³ may coordinate triglyceride breakdown and synthesis respectively in adipose tissue in response to adrenaline, in the same way that activation of phosphorylase kinase and inhibition of glycogen synthase allow coordinated control of glycogen breakdown and synthesis by adrenaline (skeletal muscle) or glucagon (liver). The activation of cholesterol esterase increases the pool of cholesterol for steroidogenesis in the adrenal cortex in response to ACTH stimulation⁷⁴. The phosphorylation of acetyl-CoA carboxylase decreases its activity and increases the K_a for the activator citrate⁷⁵. This underlies the inhibition of fatty acid synthesis in adipose tissue by adrenaline⁷⁶ and in the liver by glucagon⁷⁷. Acetyl-CoA carboxylase is phosphorylated at multiple sites and several protein kinases (including glycogen synthase kinase-5) seem to be involved^{40,75}. The inactivation of 6-phosphofructo 2-kinase^{78,79} and pyruvate kinase⁸⁰, and activation of fructose 1:6 bisphosphatase^{81,82}, appear to be crucial events in the stimulation of gluconeogenesis by glucagon in hepatic tissue. 6-Phosphofructo 2-kinase catalyses the formation of fructose 2:6 bisphosphate, a key activator of 6-phosphofructo 1-kinase and a powerful inhibitor of fructose 1:6 bisphosphatase^{83–86}

The phosphorylation of pyruvate kinase increases the K_m for phosphoenolpyruvate, makes it more sensitive to the inhibitors ATP and alanine, and increases the K_a for the activator fructose 1:6 bisphosphate⁸⁰. The phosphorylation of fructose 1:6 bisphosphatase decreases the K_m for fructose 1:6 bisphosphate⁸¹. The activation of hepatic phenylalanine hydroxylase⁸⁷⁻⁹⁰ is probably one of several mechanisms by which amino acid degradation is activated to provide gluconeogenic precursors and tricarboxylic acid cycle intermediates in response to glucagon. The activation of tyrosine hydroxylase in the adrenal gland or brain⁹¹⁻⁹³ increases the rate of synthesis of the hormones and neurotransmitters adrenaline, noradrenaline and dopamine in response to neural excitation. The Ca²⁺-calmodulin-dependent

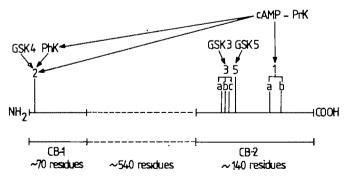

Fig. 3 Organization of the phosphorylation sites in rabbit skeletal muscle glycogen synthase. Site 2 is seven residues from the N-terminus and sites 3a, 3b, 3c, 5, 1a and 1b are 30, 34, 38, 46, 87 and 100 residues from the N-terminus of a large CNBr-peptide (CB-2) at the C-terminal end of glycogen synthase 41. Abbreviations: cAMP-PrK, cyclic AMP-dependent protein kinase; PhK, phosphorylase kinase; GSK, glycogen synthase kinase.

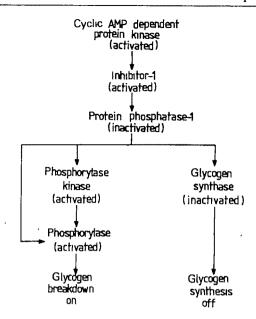

Fig. 4 Role of protein phosphatase-1 and inhibitor-1 in the β -adrenergic control of glycogen metabolism in mammalian skeletal muscle.

enzyme myosin light chain kinase is essential for the assembly of myosin into filaments and for actin-activated actomyosin ATPase activity in smooth muscle and non-muscle tissues⁹⁴⁻⁹⁶. The inactivation of this enzyme by cAMP-PrK⁹⁷ may be a key event in the adrenaline-induced relaxation of smooth muscle^{98,99}.

Of the 12 enzymes discussed above, only phosphorylase kinase, glycogen synthase and pyruvate kinase meet all four criteria necessary to establish that a protein serves as a physiological substrate for cAMP-PrK in vivo 100,101, although acetyl-CoA carboxylase 65,90 come very close to doing so.

Although it is likely that regulation by hormones of processes such as muscle contractility, secretion, membrane permeability and transport, growth and differentiation, protein induction and protein degradation also involve phosphorylation, progress is still hampered by a lack of understanding of the molecular nature of the processes themselves. Nevertheless, the importance of cAMP-PrK has been established in several cases. For example, the phosphorylation of troponin-I in cardiac muscle fibres decreases the affinity of troponin-C for Ca²⁺, and may contribute to the increased rate of relaxation of cardiac muscle produced by adrenaline⁹⁵. Similarly, the phosphorylation of a protein in cardiac sarcoplasmic reticulum, termed phospholamban, is associated with activation of the sarcoplasmic reticulum ATPase and increased rates of Ca²⁺ uptake into these vesicles^{95,102-104}. This may also promote the increased rate of relaxation of cardiac muscle by adrenaline. The growth of mammalian cells is inhibited by cyclic AMP after several days in culture, allowing the selection of mutant strains in which this phenomenon no longer occurs, and these mutant cells are invariably found to have defective cAMP-PrK activity 105,106. Thus, even the long-term effects of cyclic AMP on cell growth are clearly mediated by this protein kinase, and must involve the phosphorylation of as yet unidentified proteins.

It is important to stress that cAMP-PrK is a highly specific enzyme, phosphorylating very few proteins at significant rates. Even physiological substrates are only phosphorylated at one or two sites out of a large number of serine or threonine residues that are potentially available ¹⁰¹. The basis for this specificity has become clearer following the discovery that physiological substrates invariably contain two adjacent basic amino acids just N-terminal to the residue that is phosphorylated. This structural feature is now known to be critical for specific substrate recognition (reviewed in refs 5, 36, 80, 101).

Calmodulin: Neural and hormonal stimulation of a variety of cells produces transient rises in the cytoplasmic concentration , but only recently has it become clear that many of the biological actions of Ca²⁺ are mediated by the Ca²⁺-binding protein calmodulin, in a manner that closely resembles the action of cyclic AMP^{23,107}. The ability of calmodulin to function as a Ca2+-dependent regulator of enzyme activity is a consequence of conformational changes following its binding of Ca²⁺, which lead to the formation of specific interaction domains. Table 2 lists 12 enzymes that are activated by, or completely dependent on, calmodulin, These include a number of protein kinases or protein phosphatases, three of which (phosphorylase kinase, myosin light chain kinase and protein phosphatase-2B) have been discussed already. A calmodulindependent protein kinase in rat liver phosphorylates site 2 of glycogen synthase, but is distinct from phosphorylase kinase as it cannot activate glycogen phosphorylase¹⁰⁸. A cardiac protein kinase which phosphorylates phospholamban does so at a site(s) distinct from that phosphorylated by cAMP-PrK, and is associated with increased rates of Ca²⁺ uptake¹⁰⁹. A brain protein kinase phosphorylates tryptophan hydroxylase and tyrosine hydroxylase 110, and therefore regulates the synthesis of the neurotransmitters serotonin and dopamine. Protein-I, a major protein of the postsynaptic membrane, that may function in the control of neurotransmitter release, is a target for two different calcium-dependent protein kinases that phosphorylate distinct serine residues on the protein. Protein-I is also a target for cAMP-PrK^{111,112}. In addition, a variety of tissues contain membrane-bound calmodulin-dependent protein kinases that phosphorylate membrane proteins whose identity and function are as yet unknown 113,114

Although the cyclic AMP and calmodulin systems are formally analogous in the way in which they produce phosphorylation of a number of proteins (Fig. 5), a major difference between the two systems is that mammalian cells contain one catalytic subunit of cAMP-PrK that phosphorylates a variety of proteins¹⁰¹, whereas many different protein kinases with restricted substrate specificities are activated by calmodulin.

Another point, indicated by the broken lines in Fig. 5, is that the cyclic AMP and Ca^{2+} -calmodulin pathways are closely interlinked and may often be interchangeable in different tissues. Thus, adrenergic stimulation of glycogenolysis in skeletal muscle involves the β -receptors and is mediated by cyclic

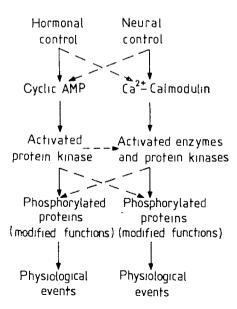

Fig. 5 Interrelationships between the cyclic AMP and Ca²⁺-calmodulin systems in the neural and hormonal control of cellular activity.

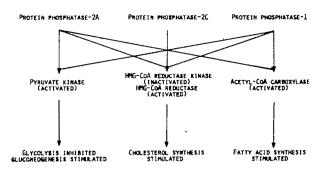

Fig. 6 Role of protein phosphatases-1, -2A and -2C in the regulation of gluconeogenesis, cholesterol synthesis and fatty acid synthesis.

AMP, whereas in adult rat liver it is an α -adrenergic effect mediated at least in part by Ca²⁺ (refs 115, 116). Similarly, electrical excitation of skeletal muscle elevates the cytoplasmic Ca²⁺ concentration, whereas it increases cyclic AMP as well as Ca²⁺ in the brain. The latter effect may result from activation of the calmodulin-dependent adenylate cyclase (Table 2) which is present in brain, but not in most other tissues.

A second point of interconnection between the cyclic AMP and Ca²⁺-calmodulin pathways is at the level of the protein kinases. Figure 5 suggests that cAMP-PrK may often phosphorylate calmodulin-dependent enzymes. The two well established examples of this phenomenon are phosphorylase kinase and myosin light-chain kinase. Further interconnection also occurs at the level of phosphorylated substrates. Figure 5 suggests that cyclic AMP and Ca²⁺-calmodulin-dependent protein kinases frequently phosphorylate the same proteins, although this will usually occur at distinct sites due to the high specificity of protein kinases (multi-site phosphorylation). Examples already discussed here are glycogen synthase, phospholamban, tyrosine hydroxylase and protein-I. Another example is 'goblin', a protein of molecular weight 230,000 in the plasma membrane of avian erythrocytes, that is implicated in the hormonal regulation of Na⁺-K⁺ co-transport¹¹⁷.

Although the importance of calmodulin in cellular regulation is firmly established, many fundamental questions remain unresolved. For example, the ability of calmodulin to activate an enzyme in vitro does not prove that this is a physiologically relevant reaction, and calmodulin may simply be substituting for another calcium-binding protein. Another question is whether different calmodulin-dependent enzymes bind to calmodulin in an identical manner, and if they do not118, might one molecule of calmodulin be able to activate several different enzymes simultaneously? Are different calmodulin-dependent enzymes activated by the same concentration of Ca2+ in vivo? This will depend not only on how many Ca2+-binding sites must be occupied in order to achieve activation, but on the amount of free calmodulin available to interact with any given enzyme^{25,119}, and on the changes in the Ca²⁺-binding properties of calmodulin that accompany its interaction with target proteins. Several calmodulin-dependent enzymes are apparently only activated when all four Ca²⁺-binding sites on calmodulin are fully occupied^{23,119}, but this requirement could be modified by phosphorylation or some other covalent modification as in the case of phosphorylase kinase. Note also that one enzyme can be regulated by two different Ca²⁺-binding proteins; this is the case for phosphorylase kinase and protein phosphatase-2B⁷⁰ and may apply frequently. All these possibilities demonstrate that the potential for very sophisticated control by Ca² exists; this could, in a sense, be regarded as the equivalent of multi-site phosphorylation.

The protein phosphatases involved in cellular regulation: One of the first pieces of evidence that implicated cAMP-PrK in metabolic processes other than glycogen metabolism, was its

high concentration in tissues where glycogen metabolism was of very minor importance. This is also the case for protein phosphatases-1, -2A, -2B and -2C in mammalian tissues 120,121. Indeed, current evidence suggests that protein phosphatases-2A, -2B and -2C may be more important in the control of metabolic pathways other than glycogen metabolism.

Protein phosphatases-1, -2A and -2C (Table 1) have broad substrate specificities⁵³⁻⁵⁵, and account for all the measurable protein phosphatase activity in mammalian liver towards L-pyruvate kinase, acetyl-CoA carboxylase, hydroxymethylglutaryl-CoA (HMG-CoA) reductase and HMG-CoA reductase kinase¹²²⁻¹²⁴, as well as the enzymes of glycogen metabolism. They therefore seem to be the major protein phosphatases involved in the control of gluconeogenesis, fatty acid synthesis and cholesterol synthesis (Fig. 6). The concentrations of protein phosphatases-2A and -2C are about threefold higher in liver than skeletal muscle^{55,121}, supporting the idea that they may be particularly important in the regulation of hepatic metabolism.

Protein phosphatases-2A and -2C have been isolated from smooth muscle as myosin light-chain phosphatases^{125,126}, and may be involved in the regulation of muscle contraction. However, protein phosphatase-1 and protein phosphatase-2B are also myosin light-chain phosphatases in vitro^{54,69}. Protein phosphatases-1 and -2A seem to be the major phosphatases acting on protein synthesis initiation factor eIF-2^{54,126} and may therefore function as stimulators of protein synthesis¹²⁷.

In view of the broad and overlapping substrate specificities of protein phosphatases-1, -2A and -2C in vitro, it is frequently difficult to assess the relative importance of these enzymes in the regulation of different metabolic pathways. In skeletal muscle, the concentrations of protein phosphatase-2A and protein phosphatase-2C are low, and it is difficult to believe that protein phosphatase-1 is not the major protein phosphatase involved in glycogen metabolism, particularly as it is specifically associated with glycogen. In the liver, the situation is much less clear. Protein phosphatase-1 is not only associated with glycogen. So, but also with microsomes 121, suggesting an involvement in processes such as cholesterol synthesis and protein synthesis. Protein phosphatases-2A and -2C are exclusively located in the liver cytosol 55,121. The former is very active towards the enzymes that regulate gluconeogenesis, fatty acid synthesis and cholesterol synthesis 122, while the latter is most active against the enzymes of cholesterol synthesis 54,122. However, these observations do not prove that they are the most important protein phosphatases acting on these substrates in vivo.

It was recently reported that microinjection of inhibitor-1 blocks the progesterone-induced division of *Xenopus* oocytes¹²⁸, suggesting that protein phosphatase-1 is responsible for a dephosphorylation event that is known to trigger the meiotic maturation of oocytes¹²⁹. Introduction of inhibitor-1 and inhibitor-2 into other cells could prove to be a powerful method for probing the biological functions of protein phosphatase-1.

The Ca²⁺-calmodulin-dependent protein phosphatase, protein phosphatase-2B (Table 1), is present at high concentrations in skeletal muscle and brain, but its concentration is low in liver^{55,121}. It appears to be identical to calcineurin (also termed CaM-BP₈₀), a major calmodulin-binding protein in brain^{70,130,131}, found in particularly high levels in the neostriatum¹³¹. Its immunohistochemical localization at postsynaptic densities and microtubules of postsynaptic dendrites¹³¹ suggests a role in the regulation of neurotransmitter action and microtubular function.

Protein phosphorylation and the control of cellular activity

The preceding sections have summarized some of the major lines of evidence that implicate cAMP-PrK, calmodulin and protein phosphatases-1, -2A, -2B and -2C in cellular processes

other than glycogen metabolism. Inhibitor-1, inhibitor-2 and glycogen synthase kinase-3 should also have more general roles as they control the activity of protein phosphatase-1. Thus, a wide range of cellular processes may respond to neural and hormonal stimuli by using remarkably similar regulatory networks that share common protein kinases, protein phosphatases and regulatory proteins.

Of course, many questions are far from being resolved. One concerns the role of 'silent' phosphorylation sites that do not appear to influence enzyme activities directly, such as the α -subunit of phosphorylase kinase or sites 1b and 5 of glycogen synthase. Two further examples are 6-phosphofructo 1-kinase^{132,133} and ATP-citrate lyase^{134,135} in rat liver. These enzymes are substrates for cAMP-PrK in vitro and in vivo, yet their functional significance remains unclear. These phosphorylations could, nevertheless, have important roles; for example, they might regulate turnover or alter the ability of these enzymes to interact with other proteins or regulatory molecules.

The most important outstanding problems concern the mechanism of action of hormones such as insulin or epidermal growth factor (EGF) (see refs 5, 136-138 for reviews), that do not appear to use cyclic AMP or Ca²⁺ as second messengers. The interaction of insulin with its receptor in the plasma membrane is known to trigger both increased and decreased phosphorylation of various intracellular proteins, and this hormone is believed to generate a second messenger that regulates a protein kinase(s) and/or a protein phosphatase(s). However, the identity of the second messenger, or the interconverting enzyme(s) that would be its primary target, has remained elusive. It would seem necessary to postulate that an insulin-stimulated protein kinase activates a protein phosphatase, or vice versa, to explain increased and decreased phosphorylation of different proteins by a common mechanism. Alternatively, the insulin second messenger might interact with two or more interconverting enzymes¹³⁹.

A further suggestion is that the insulin-receptor interaction directly activates a protein kinase, perhaps causing its dissociation from the plasma membrane. Each molecule of this protein kinase might then be able to phosphorylate many molecules of each substrate protein, allowing amplification of the hormonal stimulus without the need for any second messenger¹³⁶. The precedent for this idea is EGF. The binding of EGF to its receptor causes the latter protein to be phosphorylated by a protein kinase that is closely associated with the receptor 138 and similar observations have recently been reported for the insulin receptor¹⁴⁰. Curiously, phosphorylation of the EGF receptor occurs on a tyrosine residue. This is most unusual, as phosphotyrosine represents only 0.03% of all phosphorylated amino acids in normal cells, phosphoserine and phosphothreonine accounting for the remaining 99.97% (refs 141, 142). The phosphotyrosine content of cells can be increased up to 10-fold following transformation by some RNA tumour viruses^{141,142} and the transforming gene of several such viruses has turned out to be a tyrosine-specific protein kinase which shows intriguing similarities to the EGF-stimulated protein kinase 138,143-145. These exciting developments implicate abnormal protein phosphorylation as the cause of some virally mediated cancers.

A number of physiological stimuli that do not elevate cyclic AMP, for example, muscarinic-cholinergic stimulators, vasopressin, angiotensin and α -adrenergic stimulation, induce a rapid hydrolysis of phosphatidylinositol in the plasma membranes of their target cells, to yield inositol cyclic phosphate and diacylglycerol. It is therefore of particular interest that a new type of protein kinase has been discovered which has an absolute requirement for diacylglycerol, phosphatidylserine and physiological concentrations of Ca^{2+} (refs 146, 147). This enzyme, termed protein kinase-C, exists in an inactive form in the soluble fraction of all mammalian cells, but in the presence of Ca^{2+} associates with membranes to exhibit full catalytic activity. The Ca^{2+} dependency of this enzyme seems not to be conferred by either calmodulin or related Ca^{2+} -binding pro-

teins. It is attractive to speculate that protein kinase-C mediates the actions of several hormones, with diacylglycerol acting as the second messenger. Further work will be needed to test this hypothesis, although there is some evidence that protein kinase-C is involved in the thrombin-induced release of serotonin from platelets, and a protein of molecular weight 40,000 has been implicated as the major intracellular target for protein kinase-C in this cell^{146,147}.

Finally, I predict that the study of phosphorylation of proteins in the cell nucleus will become a major growth area over the next few years. Protein phosphorylation is very extensive in the

nucleus, but only in very few cases (histone H1 phosphorylation as a signal for mitosis 148, activation of RNA polymerase I 149) have functional roles started to be defined. I have little doubt that protein phosphorylation will be found to have many crucial roles in the control of gene structure and expression, and progress will surely be facilitated by the advances being made in unravelling the structure of the mammalian chromosome.

The work carried out in my laboratory is currently supported by a Programme Grant from the MRC, and by grants from the British Diabetic Association, British Heart Foundation and Cancer Research Campaign.

Warm saline bottom water in the ancient ocean

G. W. Brass*, J. R. Southam* & W. H. Peterson*

* Rosenstiel School of Marine and Atmospheric Science, and † Cooperative Institute for Marine and Atmospheric Studies, University of Miami, Miami, Florida 33149, USA

Considerable isotopic evidence indicates that oceanic bottom water was much warmer in the geological past. A simple convection model driven by multiple turbulent buoyant plumes and observations of present deep water formation have led to the development of a theory for the formation of warm saline bottom water. It is suggested that changes in the size and configuration of marginal seas in net evaporation zones due to lithospheric plate motions and eustatic sea level change caused these seas to become sources of warm saline bottom water. Evidence from the palaeotemperature record and palaeogeography during the late Cretaceous is used to reinforce the hypothesis. Climatic and chemical consequences of the formation of warm saline bottom water are discussed.

THE measurement of oxygen isotope ratios in benthic foraminifera from deep-sea cores has shown that oceanic bottom water has been much warmer in the geological past than it is at present—as warm as 15 °C in the late Cretaceous (about 70 Myr BP). A simple convection model driven by turbulent buoyant plumes developed by Peterson^{2,3} has led us to develop a model for the production of warm saline bottom water (WSBW). We suggest that in the geological past, changes in the size and configuration of marginal seas in net evaporation zones, due to lithospheric plate motions and eustatic (global) sea level changes, caused these seas to become sources of

Turbulent plume model

It has been pointed out that bottom water is formed in small regions. Rossby⁴ suggested that this is because convective buoyancy transfer processes are much more efficient than conductive processes. Thus, to achieve a steady state and hence no net buoyancy flux across the surface, the system evolves so that the convective processes occur on only a small portion of the surface. Moreover, virtually all deep water seems to be formed in semi-enclosed regions (over continental shelves and low- and high-latitude marginal seas)5. We suggest that water trapped in marginal seas is made sufficiently dense, by interaction with the atmosphere, for the outflow to drive a turbulent plume. 6 A characteristic of turbulent plumes is the entrainment of environmental fluid into the plume, an idea which is supported by the observation that, although the Mediterranean water at its source is denser than any water in the Atlantic Ocean, it only penetrates to about 1,200 m. Furthermore, Smith7 esti-

mated that the volume flux of the Mediterranean outflow increases by as much as 10-fold before it terminates at depth and spreads throughout the North Atlantic.

Thermohaline circulation models have tended to treat deepwater formation as a tacit assumption or as a response to global scale forcing. The importance of the outflows of marginal seas as sources of deep water suggested a simple steady-state convection model driven by imposed buoyancy sources. The model is basically the filling of a large tank whose width is very much greater than the plume width scale. The plumes interact with a laterally well mixed interior by the entrainment of interior fluid into the plumes. The model is an extension of one developed by Baines and Turner⁶.

The turbulent plume model is detailed elsewhere^{2,3} but briefly, the model calculations indicate that the depth of termination and horizontal spreading of the plumes is directly related to their buoyancy flux which is the product of the density difference between the plume fluid and the surrounding environment and the volume flux of the plume. The plume with the greatest buoyancy flux will form the bottom water and plumes of lesser buoyancy flux will terminate and spread out at intermediate depths. With two plumes, the termination depth of the weaker plume is relatively insensitive to the difference in buoyancy flux between the two until they become nearly equal in strength. Time-dependent calculations have not yet been made, but it seems that if the plumes switch (that is, the bottom water plume loses buoyancy flux or the intermediate water plume gains buoyancy flux) a relatively rapid and perhaps catastrophic change occurs when the old minor plume becomes the source for the new bottom water.

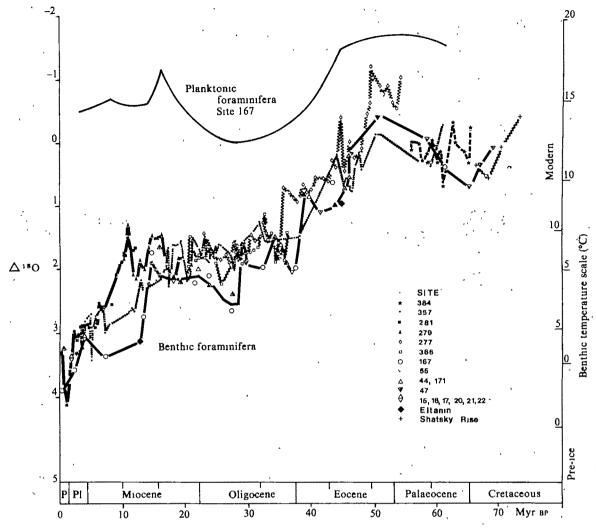

Fig. 1 Oxygen isotope palaeotemperatures from ref. 1.

Discussion

Oxygen isotopic palaeotemperature studies (on benthic foraminifera from deep-sea cores) have shown that the temperature of bottom water has decreased from ~15 °C during the Cretaceous to 3 °C at present (see Fig. 1). Superimposed on the generally decreasing isotopic temperature trend is a series of step changes—some of which are also found in the isotope record of pelagic foraminifera and have been interpreted as shifts in the isotopic composition of the oceans due to sudden increases in ice volumes. After correction for this ice effect, residual oxygen isotope shifts remain in the deep ocean which are not reflected in the surface ocean. These discontinuities in the isotopic record may be due to hiatuses in sedimentation, or they may reflect a series of shorter time scale transitions in bottom water temperature. If these step-wise changes are confirmed, Peterson's competing plume model suggests that deep water is produced by multiple sources, both warm and cold. The temperature and other characteristics of the bottom water are determined by the deep water source area that produces the largest buoyancy flux. These source strengths have varied through time due to changes in areas, location and configuration of marginal seas due to plate motions and eustatic sea level changes. We believe that in the Cretaceous, warm water sources were dominant whereas today cold bottom water is produced at high latitudes. This change necessitated at least one transition from WSBW to cold polar bottom water. However, because of the sensitivity of plume termination depths to small differences in source strengths. several transitions might be expected as a result of variations

in buoyancy fluxes from competing deep-water sources during a period in which the source strengths were nearly the same.

A simple steady-state balance calculation shows that the buoyancy flux from a net-evaporation basin essentially depends on the evaporative flux only and hence the area of the basin and the evaporation rate, and is independent of the salinity. There may be dynamic constraints on the outflow that depend on details such as the configuration of the straits that connect the basin to the ocean; but these constraints are neglected here. We suggest that at times in the geological past, the largest buoyancy flux has emanated from marginal seas in net evaporation zones.

Palaeogeographical considerations

Eustatic sea-level fluctuations can be caused by variations in the global seafloor spreading rate⁹. The area of continent flooded by given increases in sea level is a function of the global hypsography at that time. The size, and hence drainage efficiency, of the continents directly controls the shape of the hypsographic curve¹⁰. Thus, times of increased seafloor spreading and continental breakup generate large areas of flooded continent, termed epicontinental seas, both by raising sea level and by lowering the elevation of the continents.

Epicontinental seas and marginal seas producing WSBW must be located in the zone of net evaporation (10-40 °N and S) associated with the descending branches of the atmospheric Hadley Cell circulation. The distribution of Mesozoic and Cenozoic evaporite deposits strongly suggests that this zone has remained stationary during the past 120 Myr. Figure 2

shows the areas of flooded continents and marginal seas in 10° lat. intervals over the past 100 Myr as measured from the palaeogeographical maps of Barron et al. 11. The most dramatic change during this time has been the decrease in area of shallow and marginal seas in the high evaporation belt $(10-40^{\circ})$.

Because area is an important factor determining the buoyancy flux from net-evaporation basins, the decrease in the area of net-evaporation marginal seas over the past 100 Myr strongly suggests that the late Cretaceous was much more favourable for the production of WSBW. Plots of marginal sea area against time exhibit the same trend as the oxygen isotope temperature record curve from benthic foraminifera. The decrease in area of evaporating marginal seas and the decrease in the temperature of bottom water during the Cenozoic suggests a transition in the mode of deep-water formation in which cooling at high latitudes has played an increasingly important part.

Changes in the latitudinal distribution of epicontinental and marginal seas due to the motions of the lithospheric plates also occur. This movement may transport flooded regions into or out of the net evaporation belt. These movements seem to have had little effect on the areas producing WSBW in the Mesozoic (230-65 Myr BP) and Cenozoic (65-0 Myr BP), but may have been more important in earlier times.

The occurrence of WSBW would have substantial consequences for the ocean and atmosphere. The climatic consequences ^{12,13} of WSBW indicate that the suggested formation of WSBW is consistent with the equable climate of the late Cretaceous. The occurrence of a more equable climate (lesser meridional temperature gradients, with milder conditions at high latitudes) is supported by the occurrence of tropical and temperate faunas and floras, in the terrestrial record, at higher latitudes than at present.

WSBW formation complicates the interpretation of the oxygen isotope record. In the present ocean, dilution with run-off water leads to a decrease in ¹⁸O. The isotopic composition of freshwater entering the northern North Atlantic is approximately -20% and in the Arctic Ocean is about -40% (ref. 14). An understanding of the temperature, salinity and oxygen isotope effects which might be caused by horizontal salinity

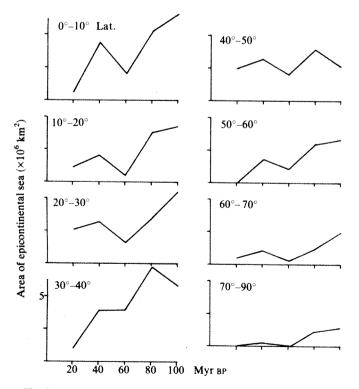

Fig. 2 Area of epicontinental seas plotted against latitude band (from the maps in ref. 11).

gradients can be derived from the consideration of a twodimensional model ocean with a homogeneous deep water containing 90% of the total volume and a surface layer containing 10% of the total. The surface layer is, on average, 5% fresher than the deep water and ranges uniformly from undiluted at the Equator to a 10% diluted at the poles. The diluting freshwater is taken to be -20% the mean salinity and δ^{18} O for the ocean are 35% and 0% respectively. We can calculate the following: the mean δ^{18} O of the surface water is -0.9% ranging from +0.1% at the Equator to -1.9% at the poles. The error in isotopic temperature calculated on the assumption that the ocean is uniformly 0% ranges from -0.4 °C at the Equator to +8.0 °C at the poles. The salinity of the surface water ranges from 35.18% to 31.66% and the deep water salinity is 35.18%. The δ^{18} O in deep water is +0.1%and the temperature error is -0.4 °C. This model assumes, arbitrarily, that the surface water at the Equator has the deep water properties. A 10% reduction in the salinity of polar surface water is sufficient to prevent sinking of polar surface water into deep water at normal salinity and a temperature of 15 °C regardless of the surface water temperature. In practice, the distribution of oxygen isotopes and freshwater in a real ocean are considerably more complicated than this model. In addition to such barriers to deep water flow as oceanic ridges and gateways, climatic and geographical mechanisms may vary the transport of water away from evaporating seas.

Conclusions

Our hypothesis has numerous consequences for the chemistry of the ocean and atmosphere. The chemical state of the ocean when WSBW was dominant would have been quite different from that which exists at present, and the effects should be recorded in the chemistry and isotopic composition of marine sediments. One immediate consequence follows from the fact that the solubilities of many gases strongly depend on temperature and salinity. The increased temperature of WSBW at its source (15 °C compared with -2 °C for present-day cold bottom water) where it is in contact with the atmosphere would reduce concentration of dissolved gases in the source water. Of particular interest are past variations in the concentrations of molecular oxygen and carbon dioxide in deep water as a consequence of WSBW. These variations should leave a signature in the accumulation rates of organic carbon and carbonate in the deep sea.

The distribution of both dissolved oxygen and carbon dioxide within the ocean is the result of exchange with the atmosphere, the formation and destruction of organic matter and physical transport processes. Respiration by animals and bacteria causes a depletion in oxygen in most subsurface ocean waters. The longer a water mass is isolated from the atmosphere the lower its oxygen content becomes; this has enabled oceanographers to use oxygen as a circulation tracer.

Anoxic conditions occur in deep water when the consumption of oxygen by organisms exceeds the rate of oxygen supply. While anoxic conditions prevail organic carbon is accumulated in the underlying sediments at a higher rate. Deep sea anoxic events have been observed in the geological record, as laminated black shales. Some authors 16,17 have explained such events by invoking stagnation resulting from a layer of fresh or brackish surface water or by expansion of the oxygen-minimum layer by inhibited oceanic circulation. These events may also be explained as resulting from a decrease in the ventilation of the deep ocean because of reduced oxygen solubility in the source regions without requiring any change in the circulation rate.

The thermohaline circulation in the ocean is driven by the interaction of the surface ocean with the atmosphere. At low temperatures, the removal of heat is accompanied by an increase in density and the production of deep water. This is the most important source of deep water in the ocean at present. At high temperatures, the addition of heat causes evaporation

and an increase in salinity and density with the same results. We believe this to have been the dominant mechanism for deep water formation in historical times especially in the Cretaceous. The physics and chemistry of the process require further study as do the implications for climate and geology and especially

Enzymatic replication of $E.\ coli$ chromosomal origin is bidirectional

Jon M. Kaguni, Robert S. Fuller & Arthur Kornberg

Department of Biochemistry, Stanford University School of Medicine, Stanford, California 94305, USA

A soluble enzyme system has been discovered which specifically recognizes and replicates plasmids containing the Escherichia coli chromosomal origin, oriC. Electron microscopy has shown that plasmid replication begins at or near oriC from which it progresses bidirectionally to completion. Control of initiation of a cycle of chromosomal replication and mechanisms of priming and fork movement can now be explored using this system.

REPLICATION of the Escherichia coli K-12 chromosome, as shown by genetic and biochemical analyses in vivo, begins at a unique site (oriC) and proceeds bidirectionally 1-3. The DNA fragment containing oriC has been isolated by its ability to confer autonomous replication on plasmids or phage whose own replication origin has been inactivated⁴⁻⁷. Deletion analysis has localized oriC to a sequence of 232-245 base pairs (bp)8; insertions, deletions or substitutions in this essential region can inactivate oriC.

Initiation of a cycle of chromosomal replication in the cell requires the activities encoded by the genes dnaA, dnaI and dnaP⁹⁻¹¹. In addition, dnaB and dnaC proteins, whose activities are essential for priming the synthesis of nascent chains during replication^{12,13}, are also required during or shortly after initiation^{14,15}. RNA polymerase has also been implicated¹⁶.

A soluble enzyme system has been discovered which specifically recognizes and replicates oriC plasmids 17. The reaction requires dnaA protein, RNA polymerase and numerous replication proteins including dnaB, single-stranded DNAbinding protein and DNA gyrase. Recently, dnaC protein has been shown to be required for in vitro replication of oriC plasmids (unpublished observations). Biochemical analysis of enzymatically synthesized replicative intermediates showed initiation occurring at or near oriC and was consistent with bidirectional progress from that point, but such evidence is essentially a statistical average. Is replication of an individual molecule, once initiated at oriC, then extended bidirectionally to completion? We present here the results of an electron microscopic study which indicate that with few exceptions this enzyme system creates an 'eye' or replication 'bubble' in a plasmid molecule at or near the oriC region which is extended in both directions to generate two complete molecules.

Formation of replicative intermediates

Two classes of supercoiled, oriC template DNA were examined. One, pSY317, is a 13.5-kilobase (kb) plasmid which contains a 5.6-kb EcoRI, oriC fragment (from pSY221)⁵ and a 7.9-kb EcoRI kanamycin-resistance fragment (from pML21)¹⁸. The oriC plasmid contains oriC intact, together with extensive flanking sequences. The second template, M13oriC26, is a 12.2-kb, chimaeric M13 phage DNA containing oriC and its adjacent

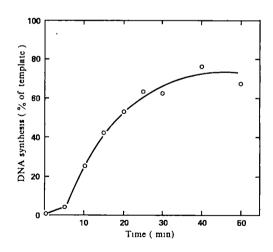

Fig. 1 Time course of oriC plasmid in dnaA-complementing conditions. Reactions were performed as described previously in a 250 µl volume containing 40 mM HEPES pH 7.6, 2 mM ATP, 0.5 mM each of GTP, UTP and CTP, 43 mM creatine phosphate, 100 µM each of dGTP, dATP, dCTP and 5-methyl-³H dTPP (85 c.p.m. per pmol of total deoxynucleotide), 6% (w/v) polyvinyl alcohol 24,000, 11 mM magnesium acetate, 100 μg ml⁻¹ creatine kinase (Sigma), 8.6 μg ml⁻¹ supercoiled pSY317 DNA, 2 mg of protein (fraction II, prepared from E. coli WM433 dnaA204 as described elsewhere 17) and 230 units of dnaAcomplementing activity (fraction III). Incubation was at 30 °C. Aliquots (25 µl) were TCA-precipitated and counted in a liquid scintillation counter. One unit is equal to one pmol of nucleotide incorporated per min.

asnA gene¹⁹. In constructing M13oriC26, the XhoI site immediately to the right of oriC was interrupted. Although interruptions in and around this site do not alter the ability of this and similar oriC plasmids to replicate^{8,19,20}, the directionality of replication was reported to be affected, becoming unidirectional rather than bidirectional^{21,22}.

The extent of replication was limited to obtain a significant number of replicative intermediates for electron microscopic study. The chain terminator, 2',3'-dideoxythymidine 5'-triphosphate (ddTTP) was used. This inhibitor, which prevents chain growth when incorporated into DNA, was present at concentrations relative to dTTP that generated replicative intermediates showing different exents of replication²³. It is assumed that incorporation of a ddTMP residue in the leading or lagging strand at a replication fork stops fork movement. DNAs were purified, spread on parlodion-coated grids by the formamide

c d

Fig. 2 Replicative intermediates of pSY31/ and M13onC26. The reaction with 8.6 μg ml⁻¹ of supercoiled pSY317 was as described in Fig. 1 legend in a 125 µl volume with 50 µM ddTTP, 1,100 µg of E. coli WM433 dnaA204 fraction II and 275 µg of E. coli HB101 (pBF101) fraction II, known to be enriched for dnaA-complementation activity17 Incubation was at 30 °C for 10 min after which reactions were terminated by addition of SDS to 1% and EDTA to 50 mM. Following incubation at 65 °C for 3 min, aliquots were removed for TCA precipitation and counted in a liquid scintillation counter. The sample was then incubated with 0.5 mg ml⁻¹ of proteinase K (Merck) at 37 °C for 60 min, phenol-extracted, etherextracted, and centrifuged in a Beckman airfuge into a CsCl shelf of 1.42 g cm⁻³. The shelf was recovered and DNA was ethanol-precipitated and resuspended in a small volume of 10 mM Tris-HCl pH 8.0 and 1 mM EDTA. Recovery at this step was 60-70% of the initial reaction product. The sample was then incubated with 5 µg ml-1 of pancreatic RNase at 37 °C for 60 min to digest contaminating RNA and either relaxed with SalI endonuclease (given by K. Burtis) in the presence of ethidium bromide31 (a), or restricted to completion with SalI endonuclease in 10 mM Tris-HCl pH 8.0, 10 mM MgSO₄ and 100 mM NaCl at 37 °C for 30 min (b). DNA was then spread on to parlodion-coated grids by the formamide technique24 shadowed at a low angle with platinum-tungsten vapour, and viewed in a Philips 300 electron microscope. Replicative intermediates of M13oriC26 were prepared for electron microscopy as described above except that the sample was either relaxed with EcoRI endonuclease (given by C. Mann) (c) or linearized by digestion to completion with EcoRI endonuclease in 100 mM Tris-HCl pH 7.2, 5 mM MgCl₂, 2 mM 2-mercaptoethanol and 50 mM NaCl at 37 °C for 60 min (d). Scale bars, 0.5 μm.

spreading technique²⁴, and rotary shadowed at a low angle with platinum-tungsten vapour. Replicative intermediates generated with an enzyme fraction (fraction II)¹⁷ from wild-type cells constituted 10–20% of the molecular forms observed, a value consistent with the fraction of template molecules used in

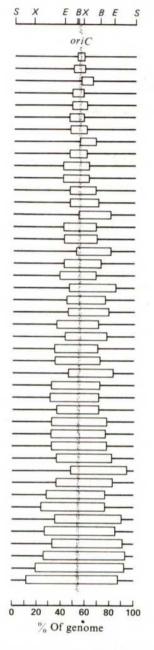

Fig. 3 Replication of the oriC plasmid pSY317 initiates at oriC and progresses bidirectionally. Replicative intermediates generated with 50 µM ddTTP, then purified and linearized with SalI endonuclease (as described in Fig. 2 legend), were randomly selected and photographed. Molecules were analysed with a Hewlett-Packard 9810A calculator by measuring the non-replicated and both replicated segments of an individual molecule on a Hewlett-Packard 9864A digitizer board, averaging the replicated segments, and expressing each portion as a percentage of the total length. Only molecules in which both replicated segments were identical in length (±5%) and for which the total length was within $\pm 10\%$ of the length expected were included in the analysis. Molecules are aligned so that the longer unreplicated segment is to the left, and they are arranged according to increasing extents of replication. The position of oriC is indicated by the stippled area. The open boxes represent the replication 'bubble'. Restriction endonuclease sites are: S, SalI; X, XhoI; E, EcoRI; and B, BamHI.

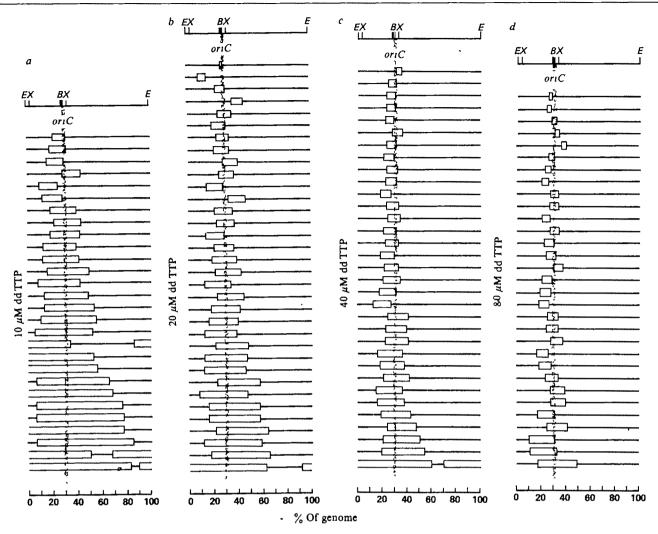

Fig. 4 Replication of M13 oriC26 DNA initiates at oriC and progresses bidirectionally. Reactions were performed as described in Fig. 1 legend in a volume of 125 μl containing ddTTP (as indicated) and 1 mg of enzyme fraction II prepared from E. coli C600 as described elsewhere 17. Incubation was at 30 °C for 15 min. Replicative intermediates produced with a, 10 μM; b, 20 μM; c, 40 μM, and d, 80 μM ddTTP from samples prepared as described in Fig. 2 were restricted, after treatment with pancreatic RNase, with an excess of EcoRI endonuclease, spread on to parlodion-coated grids and examined. Replicative intermediates at each ddTTP concentration were selected randomly, photographed and measured. Only molecules having a correct total length (±10%) in which both replicated segments were the same length (±5%) were included in the analysis. Molecules are aligned so that the longer unreplicated segment is to the right, and they are arranged according to extent of replication. The position of oriC is indicated by the stippled area. The open boxes represent the replication 'bubble'. Restriction endonuclease sites are the same as for Fig. 3.

comparable uninhibited reactions. It is possible that the fortuitous arrangement of a DNA fragment overlapping a circular molecule or unit-length linear fragment can give rise to structures that are indistinguishable from true replicative intermediates, but such events are expected to occur only rarely. Circular replicative intermediates of pSY317 and M13oriC26 appeared in every case as theta-like structures (see Fig. 2).

Defining the initiation site and direction of replication

Replication of an oriC plasmid (for example pSY317) requires dnaA protein¹⁷. Complementation of a crude enzyme fraction (fraction II)¹⁷ prepared from a dnaA mutant provides an assay for purifying dnaA protein overproduced in cells bearing a plasmid carrying the dnaA gene. In a dnaA protein preparation enriched at least 200-fold over wild-type levels, the template molecules were almost completely used in a reaction (Fig. 1).

In conditions which complement dnaA activity, replicative intermediates of pSY317 were accumulated by inhibiting the reaction by 60% with 50 µM ddTTP. To determine the site of initiation and direction of replication, molecules were linearized

by cleavage with SalI endonuclease and examined by electron microscopy (Figs 2, 3). In orienting the molecules in Fig. 3, oriC is located at a point 45% of the genome length from the right end of the linearized pSY317. With few exceptions, the replicated segment of the intermediate overlaps oriC. Although the slight asymmetry of the SalI restriction cleavage relative to oriC introduces some ambiguity in orienting the more extensively replicated intermediates, it is clear that for most of them, replication proceeds bidirectionally. Inspection of the less extensively replicated molecules reveals that initiation occurs at or near oriC. Thus, we have shown that in these conditions, replication of the oriC plasmid pSY317 proceeds bidirectionally from a start in the oriC region.

Replicative intermediates of M13oriC26 DNA were generated with an enzyme fraction (fraction II)¹⁷ from wild-type cells at several levels of ddTTP inhibition and analysed after cleavage with EcoRI endonuclease (Figs 2, 4). In uninhibited reactions, no replication occurred from the M13 origin¹⁷ due to the absence of the M13-encoded gene 2 protein required for replication of supercoiled M13 DNA²⁵⁻²⁷. Inhibition of replication as measured by nucleotide incorporation correlated well with the effect of ddTTP in decreasing the average length of the

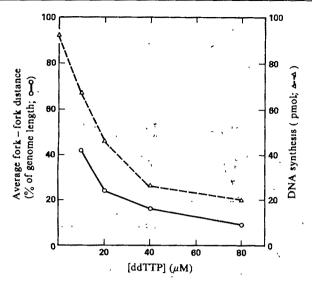

Fig. 5 Inhibition of DNA synthesis by the chain terminator. ddTTP correlates with the fork-to-fork distance of replicative intermediates of M13 or C26. After incubation, aliquots (25 µl) from the reactions described in Fig. 4 legend were removed for TCA precipitation and counted to determine the amount of DNA synthesis. The replicative intermediates of Fig. 4 were then analysed individually for the extent of replication and averaged. Each point represents the average fork-to-fork distance of 28-34 replicative intermediates generated at the corresponding ddTTP con-

replicated segment (Fig. 5). These findings and similar results for pSY317 (data not shown) confirm that the 'eye' and 'Y' forms (molecules with a single fork) are replication intermediates.

The minimal oriC sequence is ~30% of the genome length from one end of M13oriC26 DNA linearized by EcoRI endonuclease (Fig. 4). Recombinant M13 phage DNAs from which oriC has been deleted do not replicate from oriC either in vitro

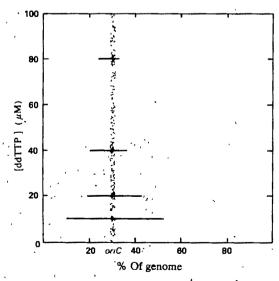

Fig. 6 Replication of M13oriC26 DNA is bidirectional for a population of molecules. Replicative intermediates at each ddTTP concentration shown in Fig. 4 were analysed individually for the extent of replication rightwards and leftwards from oriC. The values were averaged and plotted relative to the position of oriC, indicated by the stippled area, and to the physical map of M13oriC26 linearized at the single EcoRI site. Molecules (4 of 126) which did not seem to have initiated from oriC were excluded from the analysis.

or in vivo 17,28. Molecules aligned in Fig. 4 with the longer replicated segment to the right are consistent with replication initiating from the oriC segment. More extensively replicated molecules clearly indicate that replication proceeds bidirectionally in most cases, and the less extensively replicated molecules show initiation to be at or near oriC.

Replicative intermediates of M13 oriC26 (Fig. 4) were analysed individually with respect to the extent of replication to the right and left of oriC. These values were averaged for each ddTTP concentration and plotted as the distance rightwards or leftwards relative to orlC (Fig. 6). The results indicate that for a population of molecules, replication from ortC is bidirectional.

Of 126 M13oriC26 replicative intermediates examined, 4 were judged not to have been initiated at oriC as the replicated segment did not overlap oriC within the error of measurement (5% of the genome length; Fig. 4). These discrepancies may be due to aberrant initiation or improper breakage of the duplex template. For several molecules of both template DNAs, the bidirectional progress of replication appears asymmetric or even unidirectional, which may be due to asynchrony in the initiation of the two replication forks or in chain terminations by ddTTP. In this regard, examination of the replicative intermediates of phage A and F plasmids, which are known to replicate bidirectionally, also reveals molecules that replicate unidirectionally^{29,30}.

The bidirectional replication of M13oriC26, a template interrupted at the XhoI site, contrasts with the analysis of replicative intermediates of the oriC plasmids²⁰, pOC24, produced in vivo, in which predominantly unidirectional replication was attributed to an interruption at the same XhoI site^{21,22}. This discrepancy may be due to differences in either the plasmid sequences or the experimental conditions; in the in vivo study, replicative intermediates were detected at a frequency of only 1 in 10⁴ plasmid molecules and thus may not represent the principle mode of replication²¹.

This electron microscopic study of individual plasmid molecules replicated in a soluble enzyme system is thus consistent with initiation of replication from oriC. Fork movement from that point progresses bidirectionally. The soluble enzymatic system used here and elsewhere 17 should allow a biochemical approach to the events of priming, fork movement, regulation of initiation and other events occurring at the E. coli origin.

We thank Darrell Dobbertin for assistance in the electron microscopy. This work was supported in part by grants from the NIH and NSF. J.M.K. is a Fellow of the Damon Runyon-Walter Winchell Cancer Fund.

Linkage of β -thalassaemia mutations and β -globin gene polymorphisms with DNA polymorphisms in human β -globin gene cluster

Combined analysis of DNA polymorphisms in the human β -globin gene cluster and in cloned β -genes has revealed the association of specific B-thalassaemia mutations and B-gene polymorphisms with particular flanking polymorphisms. A systematic study of cloned genes identified several new mutations, one of which possibly affects transcription. The strategy used may be applicable to other diseases of single-copy genes.

METHODS of recombinant DNA analysis, including restriction endonuclease mapping, gene cloning, DNA sequencing and gene expression assays, now permit detailed study of the molecular basis of human genetic disease. Among the first disorders examined in this context were the β -thalassaemias, inherited conditions affecting synthesis of the β -globin chain of adult haemoglobin^{1,2}. Recently, several types of specific β -globin gene defects have been defined in affected individuals, including deletion of the terminal end of the gene in Asian Indians³⁻⁵, chain termination (or nonsense) mutations in Chinese and Mediterraneans⁶⁻⁹, a frameshift deletion in a Turkish patient⁷, a point mutation within an intervening sequence (IVS) in Mediterraneans^{10,11}, and an IVS splice junction mutation in some Middle East individuals 12 and a Mediterranean (R. H. Treisman, N. Proudfoot, M. Shander and T. Maniatis, in preparation). The disparate β -thalassaemia genes analysed so far have been largely unselected or at best chosen for study on the basis of their phenotype, either β^0 or β^+ , corresponding to absent or reduced β -globin production. Using this rather random approach, the full spectrum of DNA lesions responsible for a genetic disorder may not be apparent, as cloning of mutant genes from individuals having similar phenotypes is naturally biased towards the study of the most prevalent alleles. Without using a directed approach for selection of genes for further examination, the search for new, and potentially informative, mutations is encumbered by repeated analysis of previously characterized genes.

In this study, we have developed and applied a new strategy for the comprehensive analysis of existing mutations in a class of human disease. Specifically, we have combined analysis of various restriction enzyme polymorphisms in the β -globin gene cluster with direct examination of β -globin structural genes in Mediterranean individuals having β -thalassaemia. The basis of

this approach is our finding that specific mutant genes are strongly linked to patterns of restriction site polymorphism (haplotypes) in this region of the genome. Systematic characterization of genes representing all haplotypes in an extensive panel has revealed several new mutations and the nature of sequence polymorphisms within the β -globin gene itself. This approach to the study of β -thalassaemia should be readily applicable to the systematic analysis of specific mutations of other single-copy genes which result in human disease.

Restriction site polymorphisms in β -thalassaemia DNA

Several restriction site polymorphisms distributed over more than 60 kilobases (kb) of DNA within the human β -globin gene cluster have been described ¹³⁻¹⁷. In an attempt to characterize in detail the DNA regions in which mutant β -globin genes lie, we have assessed cleavage at seven of these polymorphic sites in a panel of 91 B-thalassaemia chromosomes of Mediterranean origin. Nine different cleavage patterns, one of which was found along each chromosome, were observed and designated haplotypes I-IX (Fig. 1). Individual haplotypes accounted for 1-47% of the thalassaemia chromosomes studied. When analysing the same sites in normal DNA samples, we observed non-random association of the five sites located 5' to the Bglobin gene (HincII and HindIII sites) and non-random association of the two sites located 3' to the 8-globin gene (the AvaII and BamHI sites)16. However, the 5' and 3' collections of sites appeared to associate independently to generate the various haplotypes¹⁶. In general, the polymorphic patterns in the thalassaemic DNA samples did not differ in frequency from patterns seen in normal individuals.

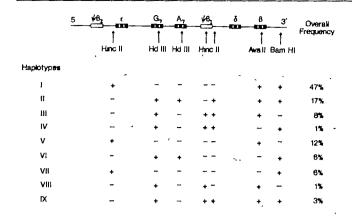

Fig. 1 Chromosome haplotypes in β -thalassaemia. Polymorphic restriction enzyme sites in the β -globin gene cluster that were used here are shown at the top in a schematic representation of the β -gene cluster. A total of 91 chromosomes of Mediterraneans with β -thalassaemia were examined at these sites by Southern³⁴ gel blotting, using methods and probes described elsewhere¹⁶. Patients were of both β^0 and β^+ phenotypes. + Indicates the presence of cleavage at a particular site, and – indicates absence of cleavage. Haplotypes indicate the patterns of cleavage along a chromosome and are arbitrarily numbered I-IX. Hd III, Hin dIII. ε , G_{γ} , A_{γ} , δ and β are the expressed genes of the cluster δ^{35} . $\psi\beta_2$ and $\psi\beta_1$ are pseudogenes identified by gene cloning δ^{35} .

On the one hand, haplotypes might reflect the presence of specific β -thalassaemia alleles in a population, in which case they would mirror the chromosomal background on which a mutation arose. On the other, several different thalassaemia mutations might be regularly found in each chromosome type, indicating no relationship between these haplotypes and specific defects.

Coupling of specific β -thalassaemia defects to specific haplotypes

In a first attempt to characterize specific mutations in β -thalassaemia, we examined randomly chosen DNA samples from patients clinically homozygous for β^0 -thalassaemia. β -Globin genes were cloned with their flanking sequences as a 7.5-kb *Hind*III fragment in bacteriophage Charon 28 (ref. 18), as previously described⁷. Surprisingly, our first three β -gene clones (one of Greek and two of Italian origin) all showed the same nucleotide substitution, within codon 39, yielding a translation stop signal 6-9 (see Table 1). Examination of the polymorphic restriction sites in the β -gene cluster of these three patients and their parents revealed linkage of the nonsense mutation genes with haplotype II chromosomes.

The coupling of one haplotype with a specific thalassaemia mutation suggested that each haplotype might indicate the presence of a specific mutant allele. Isolation and characterization of β -globin genes from thalassaemia DNAs representing the various haplotypes in our panel might then provide an efficient, systematic approach to the complete molecular description of the disorder in this population. We chose DNA samples that would permit rapid, unequivocal coupling of haplotypes with DNA mutations within β -genes. We did this by selecting patients homozygous for specific haplotypes, when available, or those heterozygous at the AvaII site located in the second intervening sequence (IVS-2)¹⁶⁻¹⁹ of the β -gene. In the latter case, by analysing bacteriophage clones containing the β -genes, we deduced which of the two β -genes had been cloned, even though the cloned region did not contain any of the other polymorphic sites used to define the haplotypes.

Further striking evidence of coupling of haplotypes and specific mutant genes was obtained for two other previously

described β -thalassaemia genes. First, three β -gene clones arising from haplotype I chromosomes contained the $G \rightarrow A$ substitution within IVS-1^{10,11} that leads to aberrant processing of precursor β -RNA²⁰ and a β ⁺ phenotype (Table 1). Second, a gene isolated from a haplotype III chromosome of a Turkish individual revealed a $G \rightarrow A$ transition at the splice junction of IVS-2 (Table 1), a mutation that prevents normal RNA processing (R. H. Treisman, N. Proudfoot, M. Shander and T. Maniatis, in preparation) and yields a β ⁰ phenotype 12. Because this mutation alters a cleavage site for the restriction enzyme HphI normally found at the IVS-2 splice junction 12,19, we analysed our DNA samples by restriction mapping with this enzyme. All of six other chromosomes of the haplotype III pattern tested demonstrated the abnormal gene map after HphI digestion,

β-Globin genes were cloned in 7.5-kb HindIII restriction fragments of genomic DNA in bacteriophage Charon 28 (ref. 18). Genomic DNA was digested to completion with HindIII and centrifuged in a 10-47% sucrose gradient in a Beckman SW27 rotor at 27,000g for 23 h. DNA of ~7.5 kb was ligated to calf alkaline phosphatase-treated HindIII arms of Charon 28 DNA and packaged in vitro into viable phage³ Phage were screened by the Benton-Davis procedure³¹ using probe prepared by nick-translation from a plasmid containing the BamHI-EcoRI fragment encompassing IVS-2 of the normal β -gene (provided by Arthur Nienhuis). The cloned β -globin genes of positive recombinants were subcloned as 4.4-kb Pst fragments in pBR322 for DNA sequence analysis. All DNA sequencing was performed by the method of Maxam and Gilbert³². Fragments were labelled at their 5' or 3' termini and either strand-separated or subjected to secondary digests before sequencing. We analysed 13 independent β -globin genes of 10 unrelated β -thalassaemic patients. Genes of haplotypes V-VIII were sequenced completely; those of haplotypes I-IV and IX were extensively sequenced, except for the central 500 bp of IVS-2. Representative examples of genes of haplotypes I-III have been sequenced completely by others (refs. 8, 10, 11 and R. H. Treisman et al., in preparation). Normal sequences are shown in parentheses above the putative thalassaemic mutations. Haplotype VI-VIII genes are separated from the others to indicate that the proposed mutations require further supportive evidence from functional studies (see text).

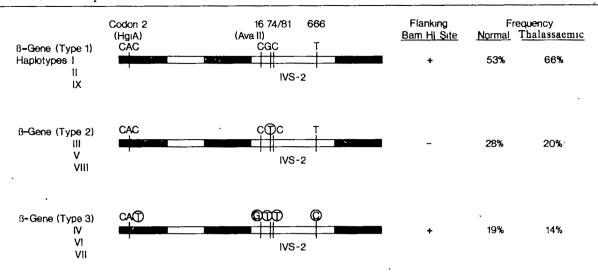

Fig. 2 β -Globin gene frameworks (gene polymorphisms). Schematic representation of polymorphic DNA sequences detected in β -globin gene clones (see Table 1). Except for the single nucleotide substitutions that lead to thalassaemia, the β -genes of haplotypes I, II and IX are identical in sequence to the normal gene sequenced by Lawn et al. ¹⁹. Nucleotide sequence differences circled in the type 2 and type 3 genes are polymorphisms on the basis of their presence in multiple β -globin genes with different primary defects (see Table 1) and by the presence of all five changes of the type 3 gene in a cloned AvaII(-) gene of a non-thalassaemic Greek individual. Type 3 genes differ from type 1 and type, 2 genes in lacking two intragenic restriction sites: the CAC \rightarrow CAT change in codon 2 obliterates an HgiA I site and the $C \rightarrow G$ substitution 16 nucleotides into IVS-2 alters an AvaII site ¹⁶.

whereas 34 of 36 β -thalassaemia chromosomes of various other haplotypes did not (see Table 2 and below). Therefore, this specific mutation was strongly coupled to haplotype III chromosomes on the basis of both gene cloning and restriction mapping.

In view of the coupling of three specific β -thalassaemia genes with haplotypes I, II and III, we analysed single genes representing the remaining haplotypes to elucidate the spectrum of mutant genes in this population. As indicated below, when possible, we assessed by restriction mapping the coupling of additional, new mutant genes with haplotypes.

DNA sequences of cloned β -genes

We examined the DNA sequence of 13 independent β -globin genes of 10 unrelated β -thalassaemia individuals, and a normal gene with the AvaII restriction polymorphism in IVS-2. Each previously undescribed mutant gene has been entirely sequenced. It is noteworthy that eight different β -thalassaemia genes were represented in the clones encompassing all nine haplotypes in our panel. Genes isolated from haplotypes IV-VIII revealed new mutations (see Table 1). Several conclusions regarding normal β -gene sequences and new putative thalassaemia mutations are derived from these data.

β-Globin gene polymorphisms: When compared with the normal gene sequence reported by Lawn *et al.*¹⁹, nucleotide substitutions that were common among different β-thalassaemia genes identified five polymorphisms of the β-sequence: a $C \rightarrow T$ substitution within codon 2, and $C \rightarrow G$, $G \rightarrow T$, $C \rightarrow T$ and $T \rightarrow C$ changes in IVS-2 positions 16, 74, 81 and 666, respectively. That these five changes are true polymorphisms was démonstrated by examining a normal gene of the $Av\Pi(-)$ variety.

Further consideration of these polymorphisms indicated the existence of three β -globin gene frameworks into which various thalassaemia mutations have been introduced (Fig. 2 and Table 1). Type 1 is characteristic of β -genes of haplotypes I, II and IX and contains no DNA polymorphisms. Type 2 genes have a single polymorphism, the $G \rightarrow T$ substitution at IVS-2 position 74, and include thalassaemic genes of haplotypes III, V and VIII. Type 3 genes, encompassing haplotypes IV, VI and VII,

display all five polymorphisms. These various gene frameworks can be identified in the Mediterranean population by restriction mapping in that type 2 genes are linked to a BamHI polymorphism. So to the β -gene (see Fig. 1 and Table 1) and type 3 genes are recognized by the IVS-2 AvaII polymorphism. By restriction mapping, we estimate that type 1, 2 and 3 genes, respectively, represent 53, 28 and 19% of β ^-genes and 66, 20 and 14% of β -thalassaemia genes in the Mediterranean population (Fig. 2).

Putative thalassaemia mutations: From their DNA sequences, we have identified eight different β -thalassaemia alleles (Table 1), four of which have been reported previously. The molecular defects of genes isolated from haplotypes I-IV are either evident from the nucleotide sequence itself⁷⁻⁹ or established by gene expression in heterologous systems (ref. 20 and R. H. Treisman, N. Proudfoot, M. Shander and T. Maniatis, in preparation). Of the new mutant genes isolated here, that present in haplotype V, which contains a G -> A substitution within the IVS-1 splice junction, is obviously a mutant of RNA processing, analogous to the IVS-2 splice junction mutant (R. H. Treisman et al., in preparation). The two genes derived from haplotype VI and VII chromosomes are also possible mutants of β -RNA processing. In particular, the single substitution within the conserved consensus sequence²¹ of the IVS-1 splice junction in the gene of haplotype VI (Table 1) may have an adverse effect on either the rate or fidelity of processing of the RNA precursor. The $C \rightarrow G$ substitution at IVS-2 position 745 in the gene of haplotype VII (Table 1) generates a new CAGGT sequence that could well serve as a new (and deleterious) internal splice site²¹ in the β -RNA precursor. The accumulation of large amounts of β -RNA precursor containing IVS-2 sequences in the erythroid cells of a β^+ -thalassaemia individual with this gene is consistent with this nucleotide change (T-C. Cheng and H.H.K., unpublished observations).

The gene isolated from haplotype VIII is a novel β -thalassaemia allele that is an excellent candidate for the first naturally occurring mutant of gene transcription in a mammalian system. Except for the IVS-2 position 74 polymorphism, its sequence is identical to that of the normal gene reported by Lawn et al. ¹⁹. Upstream from the start of the β -gene at position -87, however, a single substitution $(C \rightarrow G)$ is observed in the vicinity of the CCAAT homology²², a region which seems

Table 2 Linkage of haplotypes with β -thalassaemia mutations analysed by restriction enzyme analysis

Defect and associated haplotype	Restriction enzyme used	β-thalassaemia alleles of the specified haplotype that were positive/no. tested	β-thalassaemia alleles of other haplotypes that were positive/no. tested	β^{A} -alleles that were positive/no. tested
IVS-2 splice (III)	HphI	7/7	2/36	0/27
IVS-2 position 745(VII)	RsaI	5/6	0/49	0/42
-87 substitution (VIII)	AvrII	1/1	0/6	0/16

The presence of the specific defects was assessed by restriction mapping. For analysis of the IVS-2 splice junction mutation, the labelled probe was an EcoRI-BamHI fragment that spans IVS-2: the normal β -gene fragment is 1.1 kb and the mutant, 1.4 kb. DNA digested with RsaI was analysed with β -cDNA³³ as probe. The creation of a new RsaI site by the IVS-2 position 745 substitution reduces the length of a normal 2.2-kb fragment to 1.9 kb. A 5' β -gene probe, extending from the extragenic HpaI site to the intragenic BamHI site, was used to analyse DNAs doubly digested with AvrII and HindIII. In this case, the normal $5'\beta$ -fragment is 2.3 kb, while the mutant band is \sim 4 kb. Values are the number of alleles that were positive for the thalassaemia defect as detected by the restriction enzyme, divided by the number of alleles tested, either within a haplotype, outside it, or in the normal Mediterranean population.

The presence of specific defects was assessed by gene cloning and DNA sequencing (Table 1) and by restriction enzyme digestions using HphI, RsaI and AvrII (see Table 2 legend). Although we have cloned and sequenced only 3 genes of haplotype I, the β^+ -thalassaemia patient studied by Spritz et al. (whose DNA was given to us by B. G. Forget) was homozygous for this haplotype and is scored as one allele here. Of 34 β -thalassaemia genes that were analysed directly, 26 have been assigned a specific mutation. Within haplotype V, HphI digestion excluded the IVS-2 splice junction mutation in seven genes. If direct detection of the IVS-1 splice junction mutation in uncloned DNA were possible, as many as 33 β -thalassaemia genes out of 34 assayed might have been linked to a specific defect.

important in the efficient initiation of gene transcription^{23,24}. Functional studies of these new thalassaemia genes are in progress to establish unequivocably whether the various nucleotide changes result in the β -thalassaemia phenotype.

Although the mutations resulting in thalassaemia in the genes of haplotypes VII and VIII have not been rigorously established by functional criteria, additional restriction mapping data provide further support for the particular mutant assignments and also for coupling of these defects with their respective haplotypes. The IVS-2 position 745 substitution in the haplotype VII gene creates a new RsaI restriction site (GTAC)²⁵. Restriction mapping of both thalassaemic and normal DNAs with RsaI has been used to investigate whether this nucleotide change is a normal polymorphism and whether it is limited to haplotype VII thalassaemia chromosomes. As shown in Table 2, an abnormal RsaI map was found for five of six genes present in haplotype VII chromosomes, but in no other normal (β^{A}) or β -thalassaemia genes. The observed agreement suggests strongly that this single substitution is the primary mutation and is linked only to haplotype VII β-thalassaemia chromosomes. An additional nucleotide substitution within the 5' untranslated region of this gene (Table 1) is probably a DNA polymorphism that may subdivide framework 3 genes.

Similarly, the substitution upstream from the β -thalassaemia gene of haplotype VIII alters a normal AvII restriction site. An abnormal AvII restriction map was found in uncloned β -thalassaemia DNA of haplotype VIII but neither in β -thalassaemia genes of other haplotypes nor in β ^-DNA (Table 2).

Exceptions to simple coupling of haplotypes with specific defects

While the simplest situation would be the absolute linkage of each haplotype to a different mutation, we have found that this is not the case. We have observed two types of exception: (1) the association of a single mutation with more than one haplotype; and (2) the presence of more than one mutation within a single haplotype.

The codon 39 nonsense mutation was identified in a clone having the rare haplotype IX as well as in three clones having the common haplotype II (Table 1). The second type of exception was observed in genes of haplotype VII. As noted above, one of six genes of this haplotype had a normal RsaI restriction map, indicating the presence of another type of β -thalassaemia gene in this group. Study of the IVS-2 splice junction mutation by HphI restriction mapping revealed both types of exception. Although all of seven genes of haplotype III have this mutation, two of nine genes of haplotype V that were tested also showed this defect, whereas all of 27 β -thalassaemia genes of other haplotypes did not (Tables 2, 3). From these data, we suggest that the IVS-2 splice junction mutant comprises a minority of haplotype V B-thalassaemia genes, while the IVS-1 splice junction mutant constitutes the majority. Although the presence of the nonsense codon 39 and IVS-2 splice junction mutants in two different haplotypes is consistent with multiple, independent origins of these mutations, recombination between $\psi\beta_1$ and β -genes is a more likely alternative in view of the independent assortment of the 5' and 3' collections of restriction sites

in the β -gene cluster¹⁶. Only the finding of identical mutations in β -genes of different basic frameworks would provide clearcut evidence for multiple origins of a specific mutation.

Frequency of specific mutations and genetic heterogeneity

By combining gene cloning with restriction analysis, we have determined the specific mutation in 26 β -thalassaemia genes (Table 3). Of 20 genes associated with the haplotypes I-III and VII, 19 displayed linkage of mutation to haplotype. These four haplotypes are associated with 81% of Greek and 73% of Italian β -thalassaemia alleles. This strong relationship allows us to estimate the incidence of the various alleles in these Mediterraneans, as shown in Table 3. Molecular heterogeneity of β -thalassaemia is so extensive that only a minority of patients are homozygous for any defect. 26 of 30 Italian and 11 of 22 Greek patients were genetic compounds and not homozygotes. Haplotypes for β -thalassaemia appear to associate randomly, as the expected numbers of genetic compounds were 81% and 48% for Italians and Greeks, respectively, while 86% and 50% were observed.

Conclusions

The β -thalassaemias are among the first human genetic diseases to be examined using new techniques of recombinant DNA analysis. Previous studies used essentially unselected samples for molecular cloning and gene analysis. Genes of affected individuals were generally chosen on the basis of a clinical phenotype, that is β^+ or β^0 -thalassaemia, with little attention being paid as to whether they were likely to differ. The existence of multiple restriction site polymorphisms within the β -globin gene cluster allows the detailed characterization of chromosome regions in which mutant β -globin genes reside. Taking advantage of these polymorphisms to subdivide a panel of β thalassaemia genes, we have isolated eight different mutant genes among the nine different haplotypes represented in Mediterraneans. Repeated isolation of the same mutant gene was largely avoided by selecting β -genes on the basis of their associated haplotypes. Seven of these eight genes are present in Italians from various locales in Italy and six are present in Greeks. Our results suggest that only rare additional alleles are likely to be discovered among Mediterraneans in further studies.

The coupling of specific mutations and haplotypes is an example of linkage disequilibrium in which specific alleles become associated with neutral changes in the DNA. Disruption of these linkages could result from multiple origins of specific defects or DNA recombination (or mutation) that would alter the associated restriction site polymorphisms. As indicated above, we have found examples of discordance of single defects with haplotypes, which may have arisen by recombination.

When specimens of different racial backgrounds are examined, we find that the mutations identified in Mediterraneans are not present in chromosomes of the same haplotypes. For example, Asian Indians with haplotype III and VII chromosomes did not have the mutations recognized by restriction mapping with either HphI or RsaI (unpublished observations), although almost all samples from Mediterraneans did. Therefore, similar analyses of the kind described here may uncover new sets of mutant genes in other populations.

Our analysis of cloned genes delineates the nature of sequence polymorphism within the β -gene itself. Rather than observing randomly scattered sequence polymorphisms, we found three gene frameworks (Fig. 2) into which mutations were introduced. The presence of a common polymorphism (that at IVS-2 position 74) in frameworks 2 and 3 suggests that it may be possible to develop an evolutionary history of β -genes by analysing additional clones. The presence of these frameworks in β -thalassaemia genes, as well as coupling of specific mutations to haplotypes, suggests that the observed mutations are of relatively recent origin. We conclude that they arose after fixation of the haplotypes and β -gene frameworks.

Our data indicate that only 15 of 87 (\sim 17%) mutant genes in Italians and Greeks can be detected directly by restriction enzyme analysis in uncloned DNA using HphI, RsaI or AvrII (Table 3). Thus, direct DNA analysis of β -thalassaemia mutations will have a small impact on prenatal diagnosis in Mediterraneans unless new enzymes are discovered that recognise the common defects. DNA polymorphism analysis, on the other hand, is highly useful for prenatal diagnosis when linkage analysis within a family can be carried out 26,27. Such linkage analysis is necessary because similar haplotype patterns are associated with normal and β -thalassaemic chromosomes. The situation in β -thalassaemia is in contrast to that in sickle cell anaemia which can now be detected directly in DNA using either DdeI or MstII28,29

The coupling of haplotypes and specific mutations of a singlecopy locus within a defined population is probably a general finding as it reflects the origin of rare mutations in particular chromosomal backgrounds. We anticipate that the strategy used here will prove useful in characterizing genes associated with other inherited diseases and in further study of globin mutants. This approach should greatly facilitate the search for novel mutations among phenotypically similar individuals and the complete molecular description of a genetic disease.

This research was supported by grants from the National Foundation-March of Dimes and the NIH to S.H.O. and H.H.K. and the Cooley's Anemia Fund to H.H.K. We thank Eric Rosenvold of New England BioLabs for a gift of the restriction enzyme AvrII; David G. Nathan and John A. Phillips for critical comments; and the many physicians who have referred to us for prenatal diagnosis testing families at risk for β-thalassaemia. We thank C.N. Lewis for preparing the manuscript.

A new thermometer for external galaxies

Robert N. Martin*, Paul T. P. Ho† & K. Ruf*

* Max-Planck-Institut für Radioastronomie, D-5300 Bonn 1, FRG † Radio Astronomy Laboratory, University of California, Berkeley, California 94720, USA

We introduce a new spectroscopic method at radio frequencies to measure the temperature of giant cloud complexes in external galaxies. We have detected the $\lambda=1.3$ cm J,K=2,2 inversion transition of NH₃ in the nucleus of the galaxy IC342. This result, taken together with our previous detection of the J,K=1,1 transition allows us to deduce a kinetic temperature of 50 ± 15 K and an equivalent size scale of at least 25 pc for the molecular gas. The results are consistent with line formation in the nucleus where very active star formation is taking place.

Microwave observations of the spectral lines of various molecules have been used with varying degrees of success to derive density, temperature, size scale and mass of clouds in the interstellar medium²⁻⁴. To infer gas kinetic temperatures for molecular clouds within our own Galaxy, the lower rotational transitions (J = 1-0, J = 2-1, J = 3-2) of CO and the inversion transitions of the lower metastable states (J = K) of NH₃ have proven to be most reliable. The CO transitions (mainly J = 1-0 observations) appear to be optically thick and to be in thermodynamic equilibrium with H₂ through collisions. Thus, the brightness temperature of the line reflects the kinetic temperature (T_{K}) of the molecular cloud. The technique with NH3 utilizes the fact that the metastable states are coupled to each other principally through collisions with H2 because the radiative lifetimes between the K-ladders are very slow. Therefore one can derive from the ratios of population in several nearby metastable states a rotational temperature (T_R) which in fact closely approximates T_K . Most commonly, the J, K = 1, 1and 2, 2 inversion transitions are used with the assumption that these lines are approximately optically thin, as indicated by the relative intensities of hyperfine structures. As these two metastable doublets are close in frequency, their excitation will be similar. The ratio of antenna temperature is then (see ref. 5, for basic formulae)

$$\begin{split} \frac{T_{\rm A}(2,2)}{T_{\rm A}(1,1)} &\cong \frac{\tau(2,2)}{\tau(1,1)} \cong \frac{\nu_{2,2}|\mu_{2,2}|^2 N_{2,2}}{\nu_{1,1}|\mu_{1,1}|^2 N_{1,1}} \\ &\cong \frac{20}{9} f \, {\rm e}^{-41 \, 5/T_{\rm R}} \end{split}$$

$$N_{JK} \propto g_{JK} (2J+1) \exp(-h(BJ(J+1)+(A-B)K^2)/kT_R)$$

 $|\mu_{JK}|^2 = K^2 \mu_0^2/J(J+1)$

where τ is the optical depth, N is the column density, μ_0 is the dipole moment, g_{JK} is a statistical factor accounting for the nuclear spin of the hydrogens $(g_{JK} = 1 \text{ for } K \neq 3n, g_{JK} = 2 \text{ for } K = 3n)$, A and B the rotational constants, and f accounts for whether or not the hyperfine structure is resolved (f = 1 if unresolved).

Observationally, the ratio of the J, K = 1, 1 and 2, 2 line strengths is quite sensitive to temperature in the range 5-80 K. The empirical results show that the ratio of $T_A(1, 1)/T_A(2, 2)$ is reliable in distinguishing between regions of various temperatures. For example, $T_A(1, 1)/T_A(2, 2) \approx 1$ for H II regionlarge molecular clouds ($T_K = 30-70$ K), and $T_A(1, 1)/T_A(2, 2) \approx 10$ for dark clouds ($T_K = 10$ K). Additionally, these two transitions (at $\nu_0 = 23.7$ GHz) are separated by only 28 MHz in frequency so that they can be measured simultaneously with the same receiver and the same spectrometer. Thus, their ratio

is well determined independent of the absolute calibration of the spectra.

A comparison of the observational results of these two techniques using CO and NH₃ is shown in Fig. 1 for various types of interstellar clouds in the Galaxy. The correlation between the two methods indicates that these independent techniques are both sampling the gas temperatures. The advantage of the NH₃ observational method is that it circumvents the following difficulties, especially in extragalactic studies. First, beam dilution: the CO observations must spatially resolve the source to determine the brightness temperature reliably. In the Galaxy, interstellar CO observations generally resolve the source. However, for the external galaxies, the CO data suffer from an indeterminate amount of beam dilution. In contrast, the analysis based on NH₃ data depends on the ratio of line strengths. Because the NH₃ optical depths are in general low and the excitation for the two lines are comparable, any beam dilution effects are cancelled out in taking a ratio. Second, self absorption: several CO lines in galactic sources exhibit self absorption features due to temperature and/or density gradients in the cloud combined with the high opacity of the CO transition. Again because of the low opacities of the NH3 lines, selfabsorption effects are not observed and are not likely to be important. For the external galaxies, we therefore recognize that studies of the NH₃ molecule represent an important new

Improvements in sensitivity have allowed radio astronomers to begin to use molecular line observations to study the external galaxies⁶. CO exhibits the strongest lines and has been the most fruitful molecule for study so far. For the galaxies where the CO line is most intense, the emission has been partially mapped and serves as a tracer of the H_2 density. Thus, in combination with H I data, the total hydrogen distribution can be studied in galaxies. However, without a priori knowledge of the spatial

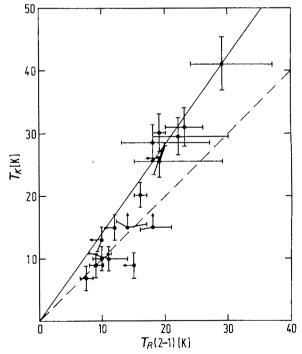

Fig. 1 A comparison of $T_R(2-1)$ as deduced from NH₃ and T_K as deduced from CO for various sources in the Galaxy^{8,9}. The dashed line is $T_R(2-1) = T_K$ and the solid line is $T_R(2-1) = 0.7 T_K$ (empirical results for compact H II regions⁸). The correlation demonstrates the reliability of temperatures derived through NH₃ measurements as compared with CO measurements. The exact coefficient is uncertain but theoretical calculations indicate that in general $T_R(2-1)$ will be less than T_K .

structures, CO cannot be used to measure gas temperatures in this instance due to the severe beam dilution. The detection of extraglactic NH₃ through its two lowest matastable transitions therefore constitutes indeed a new thermometer for giant gas complexes in external galaxies.

Using the MPIfR 100-m telescope, we have now detected the J, K = 2, 2 inversion transition of NH₃ in the nucleus of the ScD galaxy IC342, in addition to our previous detection of the J, K = 1, 1 transition¹. We can thus derive the first reliable measure of the kinetic temperature for extragalactic molecular gas. The observations were made using a cooled parametric amplifier frontend ($T_{\text{sys}} = 200 \text{ K}$) and a 256×312.5 kHz filterbank spectrometer. Both the J, K = 1, 1 and 2, 2 lines fall within the passband of the spectrometer. We detect a main beam brightness temperature of 0.032 ± 0.004 K for the J, K = 1, 1transition and 0.030 ± 0.004 K for the 2, 2 transition. Taking into account the errors in the measurements and the uncertainty in the conversion from T_R to T_K , we estimate the kinetic temperature to be 35-70 K. A detailed analysis of these results is given elsewhere7; we briefly summarize our findings as follows. From the detected brightness temperatures, we infer that the emission must cover an equivalent area with a diameter of

at least 25 pc. From excitation arguments, we derive excitation temperatures and hence densities. We then estimate the total mass as a function of size scale. Together with estimates based on the column density and abundance arguments, we arrive at a total mass detectable via the NH₃ lines of the order of $10^7 M_{\odot}$. Such large and warm gas complexes imply a large cooling rate due to emission in atomic and molecular lines. A possible heating mechanism would be warm dust grains which must first be heated by direct star light. We therefore infer the presence of numerous young OB stars. Detailed calculations indicate that 103-105 OB stars would be required in the nuclear region of IC342. We conclude that the detection of the NH3 lines, indicating the presence of warm gas, implies very active star formation in the core of this spiral galaxy. In fact, the star formation rate may be 10 times higher than within the nuclear region of our own Galaxy.

In spite of its weak lines, NH3 may be the most promising molecule, for investigations of the physical conditions of molecular clouds in galaxies.

Observing interplanetary disturbances from the ground

G. R. Gapper, A. Hewish, A. Purvis & P. J. Duffett-Smith

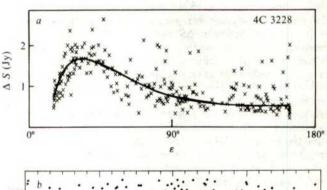

Mullard Radio Astronomy Observatory, Cavendish Laboratory, Madingley Road, Cambridge CB3 0HE, UK

The scintillation of celestial radio sources due to small-scale turbulence along lines of sight through the interplanetary medium provides a convenient, ground-based method of monitoring disturbances in interplanetary space. With the sensitive 3.6-hectare Array at Cambridge we have carried out a new programme in which ~900 sources were observed each day for more than 1 yr. When the long-term average scintillation behaviour of each source had been accurately determined we found that transient disturbances could be clearly distinguished. We detected large clouds of enhanced turbulence moving out from the Sun and were able to track them to distances beyond the Earth's orbit. Our observations differ from recent work elsewhere in that we used a larger grid of sources and observed them more continuously over a wider range of solar elongations. To illustrate the information that is now being obtained we present observations for 10-21 December 1978, a period of considerable solar activity for which spacecraft and other data are also available.

The measurements were carried out at 81.5 MHz with the 3.6-hectare Array which enables sources to be observed simultaneously at meridian transit over a wide range of declinations2. Intensity scintillation in the band 0.1-3 Hz was detected, averaged and sampled at intervals of 10 s on to magnetic tapes. The noise fluctuation per sample was ~ 0.5 Jy and each source was observed for ~120 s. Data contaminated by interference, solar noise or ionospheric scintillation were removed by a two-stage interactive program2 and the r.m.s. scintillating flux density, ΔS , was then found for the transit of each source.

To detect interplanetary space disturbances it was first necessary to determine the average systematic dependence of ΔS on solar elongation, ε , for each source as accurately as possible. Previous work³ had shown that the variation of ΔS with ε depended on the angular size of the source, rising more

steeply near the Sun for smaller sources, but measurements over 8 yr (during 1967-74) revealed no detectable solar cycle variations, nor has any significant ecliptic latitude dependence been found⁴. 250 strongly-scintillating sources were selected and ~400 daily observations of each were used to plot individual $\Delta S(\varepsilon)$ functions; smooth curves were fitted through the points by means of Chebyshev polynomials, thereby avoid-

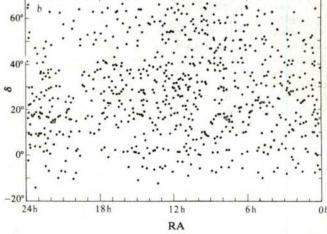

Fig. 1 a, Daily values of the r.m.s. scintillating flux density, ΔS , plotted against solar elongation, ε , for a typical source. b, The grid of radio sources observed.

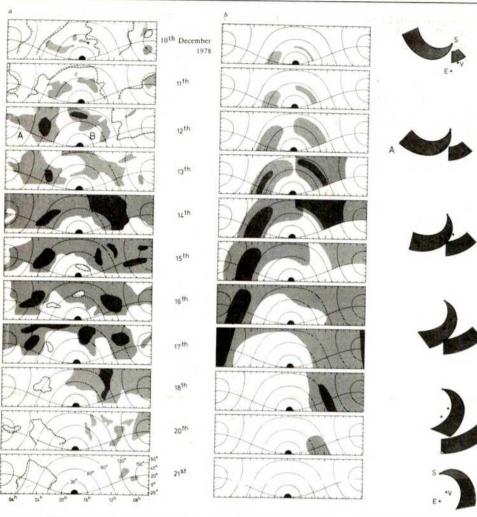

Fig. 2 a, Maps of the disturbance factor, g, across the sky. Light shading 1.25 < g < 1.5; dark shading g > 1.5. The fenced contour lines denote g < 0.5. The Sun is shown as a 15° diameter disk. b, Theoretical maps computed for the model illustrated in c. Schematic diagram of the assumed model. See also Fig. 3b. S, V, E denote the Sun, Venus and Earth.

ing possible errors due to averaging over intervals of finite elongation. The sources were next sorted into groups according to the value of the ratio $\Delta S(\max)/\Delta S(90^\circ)$ derived from the smoothed curves. Having thus separated the sources according to their angular size, daily points for the sources in each group were combined, after scaling to the same mean value of ΔS , to provide smoothed $\overline{\Delta S}(\varepsilon)$ curves. In this way we obtained a set of standard $\overline{\Delta S}(\varepsilon)$ curves against which to compare the day-to-day values of the full grid of more than 900 sources. Our method of normalization avoided the necessity of assuming some particular model of the solar plasma, although the $\overline{\Delta S}(\varepsilon)$ curves were very similar to those derived from such a model A typical $\overline{\Delta S}(\varepsilon)$ curve through the day-to-day points for a source is shown in Fig. 1a.

Interplanetary disturbances were detected by calculating daily values of the disturbance factor, $g = \Delta S/\overline{\Delta S}(\varepsilon)$, for each source in the grid shown in Fig. 1b. Maps illustrating the variation of g across the sky are shown in Fig. 2a, where approximate contours have been fitted by eye to the data. The maps are centred on the position of the Sun so that the scale of right ascension, indicated on the frame for 21 December, shifts from day to day. Note that data for 19 December are not available. The observed declination range is -10° to $+70^{\circ}$, but the frames extend to declination -20° to include the Sun, enlarged to 15° diameter, on the ecliptic. To aid visual interpretation, lines of constant solar elongation at 30° intervals are also shown. Note that the maps are not instantaneous images of the sky. The measurements take 24 h, from west to east, so that the appearance of rapidly-moving features may be distorted, as in a camera with a focal plane shutter.

Features are included on the maps only when we believe them to be real. For example, on 16 December, the small patch of decreased scintillation at $\varepsilon \sim 60^\circ$ due north of the Sun shows a well-correlated variation on all 13 sources within this zone.

When the edges of features take simple shapes, such as the boundary of the enhancement at $\varepsilon \sim 90^\circ$ on the ecliptic west of the Sun on 17 December, they can be located to an accuracy of $\pm 5^\circ$. The extent to which further details have been blurred may be assessed from (1) the relatively coarse contour intervals adopted in this preliminary study and (2) the fact that wiggles in the contours have been drawn only when they embrace correlated variations on at least five sources.

To interpret the maps in terms of three-dimensional structures in space, we first consider the constraints imposed by the theory of propagation through random media. *In situ* measurements on spacecraft^{5,6} show typical plasma density enhancements of two to three times the mean density which last for about 1–3 days. On the assumption, to be justified later, that the small-scale turbulence responsible for scintillation increases in direct proportion to the large-scale plasma density, we now consider the effect of some simple structures consistent with spacecraft data.

Figure 3a shows the location of the important scattering zones along any line of sight. The diagram refers to a particular model³ of the solar plasma but is mainly controlled by the inverse-square dependence of density with solar distance. Spherical symmetry has been assumed, for which there is good evidence over heliocentric latitudes up to 60° (ref. 4). Within a cone defined by $\varepsilon \le 45^{\circ}$ no enhanced scintillation is expected because this is the zone where scintillation saturates due to the onset of strong scattering and blurring of the diffraction pattern by sources of finite diameter. It is this which causes $\Delta S(\varepsilon)$ to decrease for $\varepsilon < 30^{\circ}$, as shown in Fig. 1a. The broken line in Fig. 3a indicates the limit beyond which any disturbance of twice the average density would give g < 1.25 and hence escape detection in our present data reduction.

Consider first a single cloud, about 0.5 AU in diameter when it reaches 1 AU, in which the density is twice the mean density

at any solar distance. Travelling at typical solar-wind speeds the cloud would cover a distance of 1 AU in about 4 days so that on successive days it might appear as shown in Fig. 3a. For lines of travel at angles $\phi \ge 90^{\circ}$ to the Sun-Earth direction, the cloud would be undetectable, except perhaps for about 1 day along lines of sight such that $\varepsilon \sim 45-60^{\circ}$. For $\phi < 90^{\circ}$ the cloud would be detectable for about 5 days. The largest enhancements of scintillation would be seen at $\varepsilon \ge 90^{\circ}$ when the cloud best fills the main scattering zone, which occurs for ϕ < 45°. To produce a disturbance lasting longer than about 5 days, the Sun must eject a succession of clouds or a continuous stream. This would take the form of a co-rotating sector, due to solar rotation, as sketched in Fig. 3a. A long-lived enhanced density disturbance of this type would be seen first to the east of the Sun and then to the west, and would be detectable for 10-12 days in all.

We found that the above constraints enabled the general form of the three-dimensional structure of the observed enhanced scintillation zones to be determined with little ambiguity. Figure 2a shows a persistent enhancement to the east (labelled A) at $\varepsilon \sim 90-150^\circ$ which lasted for 8 days. This can be explained only by the approach of a co-rotating stream. The sector must cover about $30-45^\circ$ in heliocentric longitude to account for the wide range of elongation over which it was seen on 12-13 December, and its position in longitude can be determined to $\sim \pm 5^\circ$ from the location of the sharp trailing edge, seen at $\varepsilon \sim 60-90^\circ$ near the ecliptic during 15-17 December. The extent of the sector in heliocentric latitude, which can be gauged from the rapidly increasing northward ecliptic latitude observed on 10-12 December, must be at least 45° .

The co-rotating disturbance cannot account for the enhancement (labelled B) seen above the Sun on 10-11 December and

expanding over a wide range of ecliptic latitude on 12-13 December. A and B remain clearly separated on the maps until 14 December, and the co-rotating feature discussed above could not possibly give rise to enhanced scintillation on the ecliptic at $\varepsilon \sim 90^{\circ}$ to the west on 13 December. Disturbance B. was extended roughly along lines of constant elongation and was most prominent at $\varepsilon \sim 75-120^{\circ}$ to the west on 14 December over ecliptic latitudes -20° to +90°. These characteristics indicate a tangentially extended disturbance passing Earth to the west and cutting off near the Sun-Earth line. The radial thickness of the shell must have been ~0.5 AU at a distance of 1 AU to explain the range of elongation of the enhancement on 12-13 December. Its radial velocity, derived from the outward motion of the leading edge, was $350 \pm 50 \text{ km s}^{-1}$, and the shell must have been about to engulf the Earth on 12 December. The notable increase of the enhancement on 14 December, which we interpret as due to the tangential alignment of the line of sight with the shell, indicates a spread in heliocentric longitude of at least 45°, and a corresponding extent in heliocentric latitude above the ecliptic.

To confirm these semi-quantitative estimates, we adopted the simple model shown in Fig. 3b and assumed that within each disturbance the density was doubled. The shell covered 50° in longitude and latitude above the ecliptic, and travelled at 350 km s⁻¹. The spiral envelope of the co-rotating sector corresponded to a velocity of 430 km s⁻¹ and the sector covered latitudes ±50° and 45° in longitude. In this simple analysis we ignored any interaction between the disturbances, such as might have occurred after 14 December, and computed the scintillation adopting weighting functions along the line of sight mentioned earlier. The contributions of each disturbance may be distinguished in the theoretical maps shown in Fig. 2b. Note that the shell has passed from view after 15 December. Our model simulates the observations remarkably well, considering its simplicity, and we do not believe that it could be significantly modified. Details such as the sphericity of B are not accurately known.

Before comparing our conclusions with other space and geophysical data we return to our assumption that enhanced scintillation correlates with enhanced plasma density. Much evidence now exists that enhancements of scintillation may be identified with regions of compressed plasma moving outwards from the Sun in advance of high-velocity zones. The compression regions usually occur between fast and slow solar wind streams^{7,8} or, less often, near the leading edges of disturbances associated with solar flares^{9,10}. In some cases there is evidence

that scintillation enhancements may be displaced slightly from the zone of maximum density11.

Relating our present observations to previous work, we infer that the high-velocity stream generating co-rotating disturbance A must arrive at the Earth around 17-18 December, following the departure of the compression region. The observation of a zone of decreased scintillation to the east during 18-21 December supports this conclusion, as the plasma density within fast solar wind streams has less than average density⁵. Disturbance B, which clears the Earth around 14 December, should also be followed by a zone of increased velocity.

Daily average values of spacecraft measurements and associated geomagnetic data¹² are presented in Fig. 4, together with solar plasma measurements near Venus by the Pioneer-Venus Orbiter¹³. All these observations are in excellent agreement with our model, providing further confirmation that enhanced scintillation relates to increased plasma density. A fast solar wind stream arrived at the Earth on 18 December and initiated strong geomagnetic activity. This stream was associated with a coronal hole of positive polarity which appeared on the Sun about five rotations earlier¹². Another high-velocity zone of shorter duration reached the Earth on 14 December and again caused a geomagnetic disturbance. Finally, we note that our model predicts the arrival of enhanced density at Venus on 10 December, and its departure on 12-13 December. The observed density follows this pattern, and the high-velocity zone reached Venus on 13 December, about 1 day before reaching the Earth, A shock wave at Venus was observed at 07.50 UT on 13 December, and at 01.27 UT on 14 December at the Earth¹³. This shock has been tentatively associated^{13,14} with solar flares commencing either at 23.32 UT on 10 December in McMath plage region 15697 or at 18.32 UT on 11 December in region 15694. As the wind speed rose to 500 km s⁻¹ within a few hours after the arrival of the shock at Venus, and as the shock corresponded closely with the inner boundary of disturbance B, we assume that these are related events. It is evident, however, that disturbance B could not have been generated by either of the flares because its leading edge had already advanced beyond 0.5 AU from the Sun by 12.00 UT on 10 December.

Our results demonstrate the potential of scintillation as a method of studying the morphology of interplanetary disturbances in three dimensions. The ability to track disturbances in the range 0.5-1.5 AU should be useful in the field of solarterrestrial relationships, and as a technique for predicting geomagnetic storms. The forecasting of magnetic activity depends, of course, on the early recognition of disturbances that will later engulf the Earth. In the present case we believe that the salient features of disturbance B, including the likelihood that it would hit the Earth, were evident by about 12 December, giving 2 days warning of the magnetic storm on 14 December. Similarly for disturbance A, the co-rotating nature became clear by 13 December, giving 5 days warning of the storm on 18 December.

Wave-produced bubbles observed by side-scan sonar

S. A. Thorpe, A. R. Stubbs & A. J. Hall

When a wave breaks in deep water, forming a whitecap, many small bubbles are generated and carried below the surface by turbulence. The breaking wave forms a strong acoustic target when viewed from below by an inverted side-scan sonar. The bubbles remaining in the water after the breaking wave has passed out of the sonar beam are also good acoustic scatterers and their drift towards or away from the sonar provides a means of remotely measuring that component of the near-surface current without interference of the flow and without exposing instruments to the hazard of violent near-surface conditions. This current changes rapidly as the wind changes. The sonar display shows regions of convergence or divergence of bubble clouds, perhaps associated with Langmuir circulations, and may, in calm weather, respond to the presence of surface slicks.

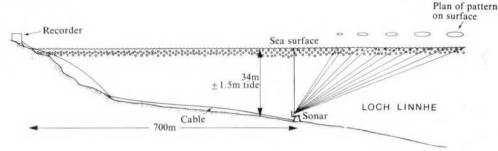

We have used an inverted telesounder¹, a modified side-scan sonar, to probe the sea surface and near-surface scatterers. The sonar consists of a single linear 248 kHz transducer mounted horizontally a few centimetres above a reflecting plate inclined upwards from the horizontal at about 20° (Fig. 1). Pulses of sound 0.08 ms (12 cm) long are transmitted at 0.25 s intervals in a vertical plane in a narrow beam which is modulated by interference with sound reflected from the plate. The pattern of the effective beam at the surface consists of a series of ovals extending away from the sonar, typically about 1 m wide and with length increasing from 1 to \sim 5 m.

The sonar was mounted by divers on a frame resting on the sea bed in Loch Linnhe, north-west Scotland, at a depth of 34 m and some 700 m from shore, to which it was connected by cable (see ref. 2 for details of earlier experiments and site). Recording was on a conventional graphic recorder displaying time versus the time delay between transmission of sound and reflected signal or effectively, for uniform sound speed, time versus range of scatterers. The beam was directed towards 290° T (true north) and, during the period of observation, the wind and swell were approximately from 225° T.

Figure 2a shows the display in conditions of low wind speed (figure times are given in Fig. 3). The return from the sea surface directly above the sonar is shown by the distinct lower dark band; in the original record both swell and wind waves can be distinguished, with periods of about 8 and 2.5 s respectively. Above the surface (at greater range from the transducer) appear a series of bands corresponding to sound scattered from the ovals on the sea surface. Their mean position is in reasonable accordance with the prediction of sound intensity shown on the right of Fig. 2a (see ref. 1 for theory). Undulations can be seen which correlate with the swell in the direct surface return. The fading of the record at the beginning and the end may be due to slicks which reduce the surface capillary waves and hence the effective scattering at 6 mm sound wavelength.

In windy conditions, the bands are overlain by parallel streaks which trend towards, or away from (as in Fig. 2b), the sonar and last for 1-5 min. Figure 2c covers a period of rapid change in pattern during a squall whilst Fig. 2d shows a more gradual change in streak direction. The streaks often start with a sharp dark line, indicating a strong scatterer moving at about 1.7 m s in these examples towards the sonar. Occasionally two such

lines are present (B, Fig. 2d). The streaks occasionally continue between bands (see, for example, Fig. 2b) indicating that the scatterers are not all in the surface ovals (as in Fig. 2a) but below the surface at shorter ranges.

The speed with which the scatterers producing the streaks move parallel to the sea surface towards the sonar is plotted in Fig. 3, together with wind speed and direction, and tidal variation (measured by the sonar). The streak speed is much less than that of phase speed of the waves (about 12.5 m s⁻¹ for swell and 3.9 m s⁻¹ for wind waves) although the lines commencing the streaks have speeds approximately equal to the component of the wind wave phase speeds in the direction of the sonar beam, which, like the wind, were always directed towards the sonar in the examples shown here. We deduce that the lines are the breaking crests of waves that produce trailing clouds of bubbles which, left in the water, are then advected by the near-surface current to form the streaks.

These bubbles have been described elsewhere^{3,4}. Most bubbles have radii of $20-150 \mu m$, have rise speeds of $<1 \text{ cm s}^{-1}$ and are concentrated near the surface². Their scattering cross-section decreases exponentially below the surface in vertical distances of 0.4-1.0 m in winds of $4-12 \text{ m s}^{-1}$. At a horizontal

range of 60 m their rise speed would contribute < 0.5 cm s⁻¹ to the current away from the transducer, which is within the accuracy to which the bubble drift can be determined from the sonar display (~1 cm s⁻¹). The speeds shown in Fig. 3 may thus be identified, to within the experimental error, as the component of the near-surface current towards the transducer. The current varies rapidly with change in wind speed (Fig. 2c). At wind speeds of about 7 m s⁻¹ (Fig. 2b) the waves break so frequently that most of the near-surface water contains bubbles which produce detectable scattering. No obvious regular patterns (like, for example, cloud streets) can be seen and the bubble population at a particular location appears to be determined principally by the earlier presence of breaking waves and advection. Clouds are typically 1-2 m wide and little lateral diffusion is apparent. Indeed, most of the streaks become gradually narrower with time, which suggests that the reduction in acoustic scattering cross-section of the clouds, due to bubbles returning to the surface or dissolving, occurs more rapidly than their lateral spread by turbulent diffusion. Small-scale convergences and divergences of the bubble streaks are, however, visible (for example at A, Fig. 2b), and these may be associated with Langmuir circulation patterns5.

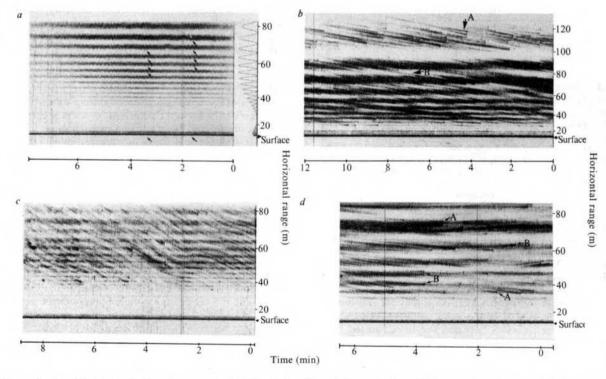

Fig. 2 Sonar displays. Note that the time increases to the left and that the non-linear horizontal distance along the surface is shown at the right. a, Low wind speeds. The arrows indicate groups of swell. The calculated intensity of a return from a uniform field of reflectors at the surface is shown at the right. The band of marks 2 min after the start of the record is due to an unknown noise source. b, The scatterers, identified as clouds of bubbles producing the streaks in the bands, are moving away from the transducer. Converging scatterers are shown at A whilst the scatterers at B are between the surface scattering bands and are therefore sub-surface. c, A squall showing a rapid variation in streak pattern. Compare with a and note the presence of (sub-surface) scatterers (bubbles) between the surface bands, especially at 4 min and 50 m range. d, A shift in current producing a change from approaching to receding streak pattern. Note the single line (breaking wave crest) commencing the streaks at A and double lines at B, where two waves in succession have broken within the sonar beam,

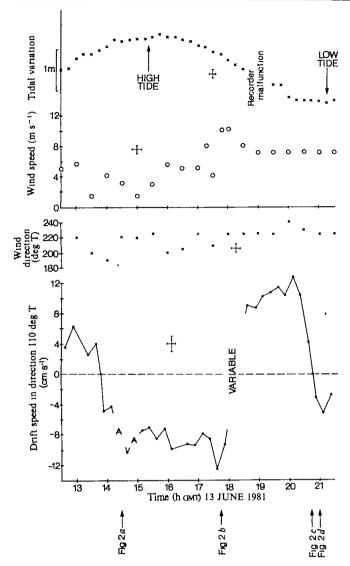

Fig. 3 The variation of tidal variation (measured from the sonar relative to an arbitrary zero), wind speed and direction (recorded at the laboratory of the Scottish Marine Biological Association, Dunstaffnage, ~1.1 km south-east of the sonar) and the 15-min average drift speed of scatterers in direction 110° T. The times corresponding to Figs 2a-d are noted on the time axis. At some times (marked A; for example, the period shown in Fig. 2a) no streak lines can be seen because the wind is not strong enough to produce breaking waves and bubbles which can be detected by the sonar.

Much of Fig. 3 can be explained in terms of wind and tide. The positive component up to about 1330 h is consistent with both wind and tidal flow. A southwesterly tidal flow should develop 1 h 50 min before high tide⁶ and indeed appears as a negative component at 1345 h slightly delayed, perhaps by the opposing wind. The increasing wind at 1745 h produces a change in current direction which continues for 3 h but then

The mean time intervals between the lines formed by the breaking crests decrease with increasing wind speed and are in accordance with earlier observations of bubble clouds⁷. Wind waves are, however, seen to break more frequently than bubble clouds appear to be generated, and it appears that only the more vigorously breaking waves may be detected by the present sonar.

The method of determining near-surface currents by remote acoustic sensing may have particular value in severe wave conditions when the signal-to-noise ratio is enhanced because more bubbles are produced and when conventional moored instruments are prone to considerable hazard and error due to mooring motion. The technique may be useful in measuring the sea state and frequency of wave breaking, as well as perhaps monitoring slicks or coastal fronts and internal waves which modulate the near-surface currents.

Storm trajectories in eastern US D/H isotopic composition of precipitation

James R. Lawrence*, Stanley D. Gedzelman*†, James W. C. White*, Daniel Smiley‡ & Paula Lazov*

The isotopic content of precipitation falling at a point provides information of potential importance concerning atmospheric circulation and climate change 1-6. The isotopic content of precipitation, however, is controlled by the particular meteorological processes acting at a given time and place and is subject to considerable variation. We have measured the deuterium-tohydrogen ratios (D/H) of precipitation at Mohonk Lake, New York, from individual storms over a 2-yr period, July 1977-June 1979. These ratios varied systematically with the locus of the paths followed by the storms: the more seawards (and southerly) the paths and the colder the temperatures at Mohonk, the lower were the D/H ratios.

Very large differences in the D/H ratios from storm to storm were observed. The δD range for all storms was -7% to -170% $\delta D = (D/H \text{ sample} - D/H \text{ SMOW})/(D/H \text{ SMOW}) \times 10^3$ where SMOW is standard mean ocean water. In general the storms with the highest deuterium contents occurred during the warm summer and early autumn months while the storms with the lowest deuterium contents occurred during the cold winter

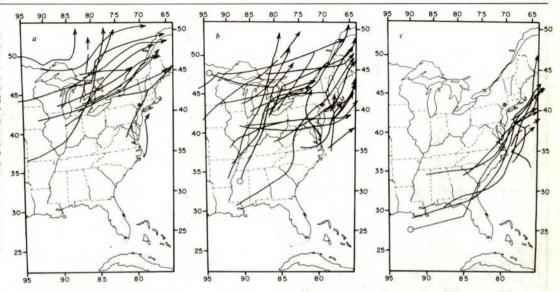

There was a large to small range of δD values during single storms. During two storms on 20-21 January 1978 and 25-26 January 1978, precipitation was also sampled sequentially at a separate location in Palisades, New York. For the storm of 20–21 January, the δD for the first 2 inches of snow was -177%, while the ice crust formed by a mixture of the later snow with freezing rain that fell at the end of the storm had a δD of -75%. For the storm of 25-26 January 1978, the δD for the first $\frac{1}{2}$ inch of rain was -78% compared with -54% for the last $\frac{1}{2}$ inch. We detail elsewhere how meteorological analysis can be used to explain the δD ratio of cyclonic precipitation at a given time.

We have found that a strong relationship exists between the isotopic content of precipitation at Mohonk for a given storm and the path taken by the storm (the storm track or trajectory): in general the 8D decreases systematically as the locus of the storm trajectories is displaced seawards (Fig. 1).

Storms in the eastern US are frequently produced as a result of the interaction of cool, dry continental air with warm, humid maritime air. There is often a rather narrow and sharp transition zone, known as the polar front, that separates these two distinct air masses. Cyclones occur more frequently along the polar front.

During the colder half of the year when the area of polar influence expands and the meridional temperature gradient is

Fig. 1 The trajectories of the low pressure centres of storms occurring between July 1977 and June 1979. The trajectories were separated into five groups on the basis of the 8D of the precipitation that fell at Mohonk Lake near New Paltz, New York. Three of the groups are shown: a, δD≥ -30%; b, $\delta D = -61$ to -90%; c. $\delta D \leq -121\%$. The two intermediate groups (isotopic ranges: -31% to -60%, and -91% to -120%) not shown have trajectories intermediate to those shown. S, The location of Mohonk Lake. O. The origins of two storms of January 1978 from which a sequence of samples was taken at Palisades, New York.

larger, the polar front is typically located further south and is more often well defined. Accordingly during the winter both cyclone frequency and intensity are greater and the average position of the paths taken by the cyclones are located further south. For the eastern US this means a greater percentage of storm tracks with coastal or offshore positions during the winter.

Similarly, during the height of the ice ages, the area of polar influence was greatly expanded and the average position of the storm tracks was much further south than today⁸. Therefore a greater percentage of the ice age storms would have been classified as coastal storms and would have produced precipitation at New York and on the North American ice cap with correspondingly low values of δD .

There is a straightforward explanation for this relationship between the δD of precipitation and position of the storm tracks. Air undergoing condensation from cooling due to lifting experiences a progressive depletion of the heavy isotopes ^{1,9,10}. Thus the precipitation from a given air parcel that forms last, or at greatest altitudes, invariably has lower δD and $\delta^{18}O$ values than any earlier precipitation from that air parcel ¹. When a frontal surface is aloft, most of the precipitation forms in the air above the front. It follows then that the higher the frontal surface, the lower the δD of precipitation tends to be. In general the higher the frontal surface above a particular location, the further south the storm is from that point. Storms that stay far to the south or remain well seawards of New York will tend to have the lowest δD because the frontal surface is always found at considerable altitude.

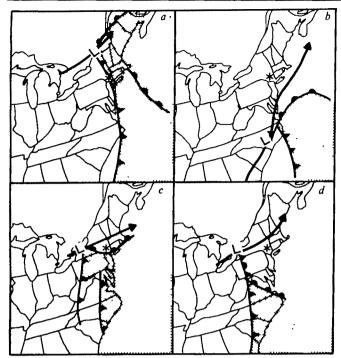

These observations lead us to predict a coherent spatial distribution of δD values around a typical extratropical cyclone. The D/H ratios should be highest for the precipitation in the warm sector of the storm, although they may be subject to some variations because much of the precipitation in the warm sector can be convective. The steep slope of the cold front should cause a dramatic decrease of the δD to the west of the surface position of the cold front (such behaviour has been described elsewhere 11). Northwards of the warm front there should be a coherent but gradual decrease of δD consistent with the gentler slope of the warm front.

Such a synoptic pattern of δD values can be used to account for the rather wide range of storm track positions for those storms producing intermediate δD values (as in Fig. 1b). Two storms may have very similar tracks but quite different δD values if the positions of the warm fronts are different. This is illustrated in Fig. 2, in which four separate storms together with their storm tracks are shown. When storm tracks are either far north or far south of Mohonk, there is little ambiguity about the δD values. However, for storms with intermediate tracks, the position of the warm front is critical for determining δD .

Figure 2a shows the storm of 9 January 1978; the track lay far north of Mohonk Lake and, as is characteristic for such

the 8D values are given for four different storms. a, 9 January 1978, 12.00 GMT, 8D = -48; b, 20 January 1978, 1.00 GMT, 8D = -145; c, 15 December 1977, 00.00 GMT, 8D = -44; d, 2 January 1978, 00.00 GMT, 8D = -145; d, 20 January 1978, 00.00 GMT, 8D = -113 The shaded region shows the warm sector of the storms. Heavy arrows show storm trajectories. *, The collection site at Mohonk Lake, New York.

storms, most of the precipitation at Mohonk occurred as rain in the warm sector or near the warm front. Such storms mostly produce a high δD.

This is to be contrasted with the storm of 20 January 1978 (Fig. 2b), which took a far more southerly track. Throughout this coastal storm, Mohonk Lake remained deeply embedded in the cold air. Characteristically, the precipitation fell amost entirely as snow (it was a major snow storm for the entire northeastern US) and 8D was very low.

Figure 2c, d shows two storms with intermediate and almost identical tracks but with a large difference in the 8D values for each storm which is a direct result of the difference between the positions of the warm fronts for each storm. The storm of 15 December 1977 (Fig. 2c) had a quite high value of δD. Most of the precipitation fell when the warm front lay only a short distance south of Mohonk. In contrast, the warm front for the storm of 2 January 1978 (Fig. 2d) remained well south of Mohonk through the time of the precipitation and consequently the 8D value for this storm was much lower.

We have also found a significant relationship between the δD values and the mean effective temperature during the precipitation. The quantity \bar{T} is calculated by weighted averaging of the temperature using precipitation amounts. Then, for January, storms with at least 0.75 inches of precipitation, we obtain

$$\hat{\delta}D = -119.5 + 5.0\bar{T} \tag{1}$$

where δD is the expected value of δD (in %) and \bar{T} is in °C. The correlation coefficient is 0.91, which is surprisingly high considering that we are relating a surface parameter to a process occurring above ground level. For most large January storms the principal maritime source is the warm waters extending from the Gulf of Mexico through the Caribbean Sea to the Atlantic Ocean. Source conditions vary rather little from storm to storm but temperatures at New York may vary considerably. Apparently the temperature at New York during times of precipitation in January varies coherently with the frontal position and with the important precipitation producing processes aloft.

Two distinct results of the present findings have great potential value. First, the isotopic composition of the precipitation from a given storm depends strongly on the details of the storm's path, structure and evolution. We have shown previously that by taking these details into account, we can calculate accurately the isotopic composition of precipitation falling at a given time and place. This shows that the δD values of precipitation or vapour in the air act as a tracer of atmospheric motions. The δD value depends most strongly on the vertical profile of the ascent rate of the air in the cloud which cannot be measured directly at present. The measurement of δD at a given time. therefore, provides a means for estimating the vertical profile of the ascent rate of the air in the clouds above.

Second, a climatic signal can be extracted from the δD values of precipitation from storms. Changes in atmospheric circulation redistribute the trajectories of storms (Fig. 1) and/or the amounts of precipitation (Table 1) in both time and space. An integrated sample of precipitation or a portion thereof provides the isotopic signal recorded in tree rings, freshwater fossils or glacial ice cores. Routine analysis of all storms would provide a better foundation for evaluating climate change from isotope

The Hadar fluvio-lacustrine formation (Ethiopia) contains an original hominid fossil Australopithecus afarensis and an abundant vertebrate faunal assemblage^{1,2}. The formation^{3,4} consists of a 150-300 m thick sequence of fine-to-coarse detrital sediments, originating from the Ethiopian Plateau escarpment, with some interbedded pyroclastic layers. The three lower members of the formation were formed in a lacustrine environment, which was occasionally interrupted by fluvial drainage. The upper member is quite distinct and formed as an alluvial fan delta. This sedimentary sequence was deposited at the end of the Pliocene between 3.9 and 2.7 Myr, as indicated by magnetostratigraphy⁵ (the palaeomagnetic record spans the Gilbert-Gauss transition period), K/Ar dating^{6,7} and biostratigraphy⁸. We consider here the oxygen and carbon isotope variations observed throughout the formation and their palaeohydrological implications.

Eighty-six carbonate horizons and 28 mollusc-bearing units were collected throughout the section, from the base to the top. The carbonates are mainly lacustrine nodules. However, at the base of the first member some micritic limestone beds occur and one horizon of the second member contains stromatolitic structures (oncolithes). These carbonates consist of a low magnesian calcite.

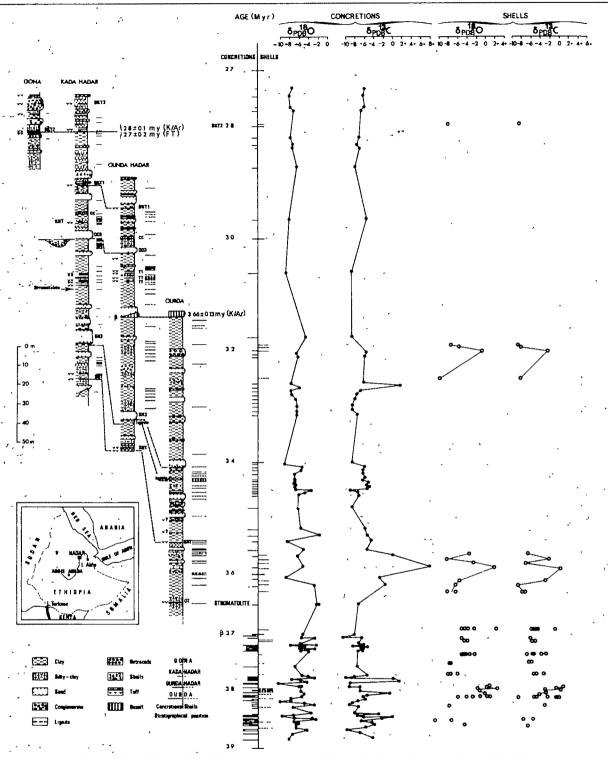

Fig. 1 The Hadar Formation. Lithology, chronology and isotopic changes in concretions and fossils.

The fossils which were collected are essentially shallow freshwater gastropods (*Melania tuberculata*, *Bellamya* sp., *Cleopatra* sp.) and a bivalve (Unionidae). The shells are usually pure aragonite and do not show any evidence of post-depositional recrystallization.

The δ^{18} O_{PDB} values, from the base to the top of the section (Fig. 1), show large fluctuations between -10.8 and -2% for concretions and between -10.5 and 2.5% for shells. These values indicate highly variable palaeohydrological conditions during the episode, with phases of drastic evaporation inducing considerable enrichment of the water in heavy oxygen. The shells are systematically enriched in 18 O compared with the concretions. This enrichment reflects both the aragonitic nature of the shells which represents a 0.8% difference with calcite

and the adaptation of molluscs to highly evaporated waters. For example, five species found within one single layer of the second member (Fig. 1) have δ^{18} O values ranging from -6 to 1%. Specific fractionation cannot explain such large differences, which are more realistically explained by environmental changes both in time and space, with conditions ranging from freshwater to highly evaporated and eventually brackish water. Most of these molluscs currently tolerate such conditions (see, for example, refs 10, 11 for Pleistocene Saharan lakes, or ref. 12 for rift lakes). That hydrological changes were very frequent in the Hadar lake, is shown by the 18 O variations in the stromatolitic structure (Fig. 2). It is difficult to assess any periodicity for the growth of oncolithes, but seasonal or annual cyclicity might be considered for those of biogenic origin 13,14 ,

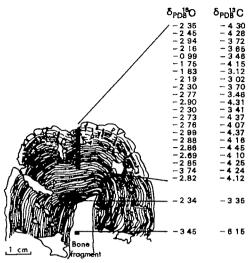

Fig. 2 Isotopic variations in one of the oncolithes of the second member.

which seems to be the case here as indicated by the ¹³C content (see below). Thus within a few years, changes as high as 3% (Fig. 2) occurred in the ¹⁸O content of calcite, these should essentially reflect variations of the isotopic composition of the lake water. An increase in temperature is not likely to be responsible for a large negative shift of ¹⁸O content in carbonates, because it would be largely counterbalanced by a positive effect associated with increased evaporation. Negative shifts of ¹⁸O values are more realistically explained by influx from precipitations. Consequently, positive shifts, from the lowest δ^{18} O values to higher ones, must essentially be the result of evaporation periods which followed the precipitations. Thus variations in the 18O content of carbonates can be related to contrasted hydrological regimes. Abundant precipitation induced sudden lake level rises; the isotopic composition of the water during such episodes was occasionally as low as $-12\pm1\%$ (SMOW), if we accept for calcite precipitation an average temperature ~25±5°C, as suggested by faunal requirements15. Periods of high lake levels were rapidly followed by isotopic evolution typical of closed basins: the evaporation induced an enrichment of the water in ¹⁸O, with δ ¹⁸O values as high as 0%. Such rapid hydrological changes suggest that the lake was mainly fed by strong floods coming from the Ethiopian Plateau escarpment. This agrees with the facies distribution which also indicates rapid changes in the sedimentary dynamics.

Similar hydrological regimes were observed in nearby Holocene lakes by Fontes and Pouchan¹⁶ or Gasse *et al.*¹⁵. The δ^{18} O values of Lake Abhé water for the Holocene¹⁷ are close to our mean values, although the range of variation there (-11.9)to -5.8%) is not as large as it was in the Pliocene Hadar lake. The similar morphological situation in the Afar Rift, and the strong influence of runoff and drainage from the Ethiopian Plateau are common to both lakes. However, the higher δ^{18} O values which were occasionally present in the Hadar lake water suggest stronger evaporation phases at the end of the Pliocene leading occasionally to subaerial conditions. The occurrence of the flood plain facies which sporadically interrupt the lacustrine sequence of the three lower members supports this interpretation. The upper member, which is characterized by coarse alluvial fan deposits, does not show large isotopic changes. The relatively stable δ^{18} O values of carbonates (-8 to -6%) indicates a fast drainage system without any strong influence of evaporation. Thus the ¹⁸O content of carbonates could reflect the average isotopic composition of the precipitation during this episode ($\delta^{18}O \approx -8.5\%$).

The ¹³C content of carbonates (Fig. 1) suggests a noticeable contribution of biogenic CO₂. A few concretions or shells show positive isotopic compositions for carbon, however, it is difficult to accept equilibrium with atmospheric carbon dioxide. Such positive $\delta^{13}\hat{C}_{PDB}$ values are linked to sedimentological features

indicating a reducing environment (with lignite layers, for example), and thus to an unusual CO₂ metabolism¹⁸

In conclusion, isotopic compositions of the Hadar lake carbonates do not reflect climatic conditions drastically different from those which prevailed during the Holocene in the area15. The lowest δ^{18} O values calculated for lake water indicate either a cold origin of the waters precipitated between 2,000 and 3,000 m on the Ethiopian Plateau, or a pronounced continental effect. A similar meteorological pattern of monsoon rains produced by cooling of humid air masses which could originate from the Gulf of Guinea, the Indian Ocean or exceptionally the Gulf of Aden, may have prevailed during the late Pliocene. The variability observed in the Hadar lake regime strongly suggests either a more contrasted seasonality as it has been proposed for the same epoch in Laetoli, Tanzania¹⁹, or longer term climatic oscillations, or both. The hydroclimatic evolution of the Afar Rift through time seems to differ from that proposed by Cerling et al.12 for the Gregory Rift more to the south in Kenya. Their data in Lake Turkana support the hypothesis of a more humid period during late Pliocene. The inland situation of Lake Turkana could explain the difference between the two areas. However, the limited number of data presented and the various origins of the carbonates (shells, lacustrine and soil nodules) analysed in both areas preclude a detailed comparison of the two sites.

The palaeomagnetic data of the Hadar Formation have been computed again and calibrated with new radiometric dates⁶. The Cochiti events of the Gilbert period and the Kaena and Mammoth events of the Gauss normal period seem to be present in the Hadar sequence. T. J. Schmitt, A. E. N. Nairn, J. L. Aronson, R. C. Walter, M. Taieb, and J. J. Tiercelin are all involved in this new study.

We thank the Ethiopian Government. This study was supported by CNRS, Fr. (A.T.P. 042) and CRSNG, Canada. Comments by H. Faure, J. C. Fontes and J. Bourne considerably improved the manuscript. T. E. Cerling helped to clarify several aspects of this final version.

Bacteria accumulate silver during leaching of sulphide ore minerals

F. D. Pooley

Department of Mineral Exploitation, University College, Cardiff, Newport Road, Cardiff CF2 1TA, UK

Silver is extremely toxic to a wide range of bacteria 1-4, and has even been used in solution to control bacterial growth2. In an investigation of the oxidation of several sulphide minerals containing traces of silver by a mixed culture of Thiobacillus ferroxidans and Thiobacillus thiooxidans, it was noted that the bacteria accumulated silver. I report here that careful collection of most of the cells from such experiments yields a silver

concentrate, while the silver attached to the cells remaining in contact with leach residues is readily recovered by a conventional cyanidation technique. These results suggest that the bacterial leaching of valuable and non-valuable sulphide minerals in order to release atomically bound silver, and possibly gold, may be used as part of a recovery process for these elements.

Electron microscopic examination of bacteria collected from several experimental sulphide leaching systems, in which substrates contained silver, has shown that the bacteria involved in the leaching can accumulate silver in very large quantities and that their activity does not appear to be inhibited by silver contained in sulphide minerals. The manner in which silver is accumulated by the bacteria is illustrated in Fig. 1, which shows an electron micrograph of a single bacterial envelope prepared by washing a mixed culture of active bacteria collected from a sulphide leaching experiment with dilute KOH. The membrane is covered with small electron-dense particles of silver in the form of silver sulphide. These small AgS granules have been observed to grow on the surface of bacteria collected at different stages of a batch leach finally accumulating to form large clumps. Cleaned suspensions of bacteria coated with such particles are very dark compared with normal bacterial suspensions and on drying at 100 °C, a shiny black deposit is produced. The amount of silver accumulated per gram of dry weight biomass varies in proportion to the silver content of the sulphide mineral being leached, but concentrations greater than 250 mg per g have been observed. The granules on the bacterial surface were analysed using a Philips EM 400 electron microscope microprobe analyser and were found to contain silver and sulphur in proportions suggesting the formulae Ag₂S. The granules are crystalline and results of polycrystalline electron diffraction indicate that the compound is the silver mineral acanthite $(Ag_2S).$

When initially observed on the surface of bacteria recovered from a sulphide leaching test, these small silver sulphide particles were considered to have been released from the matrix of the sulphide mineral being leached, and to have remained unoxidized. This hypothesis was supported by the fact that silver sulphide is unaffected by the action of acidophilic bacteria3. Further experimentation, however, has shown that these silver sulphide particles can be produced artificially on the surface of bacteria by adding silver in a soluble form to a suspension of bacteria which are actively oxidizing a sulphide mineral substrate containing no silver. The particles have also been observed forming on bacteria attached to the flat surface of silver-rich copper sulphide mineral (tetrahedrite) that had been introduced into a bacterial suspension growing on a sulphide mineral substrate free of silver. Attempts to obtain similar results with bacteria grown in the presence of ferrous sulphate alone have been unsuccessful but these silver sulphide particles

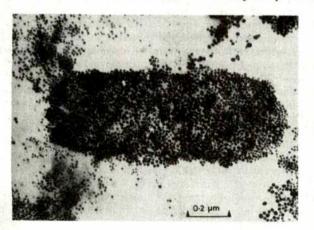

Fig. 1 Electron micrograph of a single bacterium emptied of its cell contents showing adhering silver sulphide particles, after recovery from a sulphide mineral leaching experiment in which the mineral contained trace quantities of silver.

can be formed on cells grown on elemental sulphur. Therefore, prerequisite for the formation of these particles is the presence of sulphide anions as well as silver cations. The reasons for the preferred nucleation of the silver sulphide on the bacterial wall are not clear but this preference is evident from the fact that in some experiments as much as 25% of the bacterial mass recovered after leaching of a silver sulphide mineral consisted of silver.

The finding reported here has interesting practical applications for the recovery of silver from sulphide ore minerals and is also of interest geologically, as it may indicate how silver was released, concentrated and relocated in surface ore deposits which previously had been affected by bacterial action.

Mineralization of organic matter in the sea bed—the role of sulphate reduction

Bo Barker Jørgensen

Institute of Ecology and Genetics, University of Aarhus, Ny Munkegade, DK-8000 Aarhus C, Denmark

The bacterial reduction of sulphate to sulphide at the sea bed is a key process in the oceanic sulphur cycle, and is responsible for the oxidation of organic matter which becomes buried below the oxic and sub-oxic zones of the sea bed. The oxic surface layer of the sea bed varies in thickness from a few millimetres in sheltered coastal areas to ≥1 m in pelagic sediments 1.2. Below this layer, organic matter is mineralized mainly by fermenting, denitrifying, sulphate-reducing and methane-producing bacteria. Sulphate reduction is the predominant terminal step in the mineralization processes of sulphate-rich shelf sediments where the sulphate reducers inhibit the methanogens by competing with them for common substrates3-5. Sulphate reduction may therefore have a quantitatively important role in the overall oxidation of organic matter in the sea bed. Recently, concurrent measurements of oxygen uptake and sulphate reduction in a coastal sediment have demonstrated the importance of the sulphate-reducing bacteria in the mineralization of organic carbon. I present here the first comparative survey of aerobic and anaerobic mineralization in the sea bed based on direct rate measurements of the two processes. The results demonstrate a surprisingly high contribution from the sulphatereducers. In coastal sediments, this specialized group of bacteria oxidized as much organic matter to CO2 as did all the aerobic organisms. Their relative contribution decreased three fold over the continental shelf from the shore to a depth of 200 m.

Oxygen consumption and sulphate reduction were measured in shelf sediments using previously described techniques7 Sediment cores were collected from 58 stations during cruises in Danish fjords and in Kattegat and Skagerrak, the two seas connecting the Baltic Sea with the North Sea. Measurements were made in the laboratory or onboard ship within 1 day after sampling. Sulphate reduction was analysed down to 15 cm depth in the sediment; measurements in cores of 2-3 m depth showed that most of the activity (75-95%) occurred in the topmost 0-15 cm (data not shown). Below 15 cm depth, I found significant (up to 40%) reduction only in cores from 200 m

Figure 1 shows the data obtained from all the sediment stations. The sediment types consist of a wide range of grain

sizes (from medium sand to clay) and organic content (0.7-18% dry weight). There is a clear correlation between the measured rates of oxygen consumption and sulphate reduction in these shelf sediments. This is partly a result of their mutual regulation by the influx of organic matter to the sea bed through sedimentation from the water column⁹⁻¹³. It is also due to the following inherent coupling between the two processes. During the bacterial reduction of sulphate, H₂S may be produced in large excess over the binding capacity of iron. The fraction of the H₂S which was precipitated by iron and converted into pyrite was calculated from the total (solid phase) reduced sulphur accumulation with depth and from the sedimentation rates (ref. 6 and B.B.J., unpublished results). The fraction varied from \sim 5% at 0-2 m depth to 10-20% at 20-200 m depth. Thus, an excess, corresponding to 80-95% of the H₂S produced, must have been re-oxidized back to sulphate at or near the sediment surface. The dark uptake of oxygen, which was the ultimate electron acceptor for the sulphide oxidation, therefore included 80-95% of the mineralization via sulphate.

This has important implications for the oxygen consumption of the coastal sea bed. The molar ratio of oxygen uptake to sulphate reduced averaged about 4:1 in sediments at 0-2 m and 2-20 m water depth (Fig. 1, broken line). As the oxidation capacity of 1 mol of sulphate is equivalent to 2 mol of oxygen, the ratio was 2:1 in terms of electron flow. Because 90-95% of the sulphide produced at 0-20 m depth was re-oxidized by oxygen, this means that $\sim 50\%$ of the oxygen uptake was

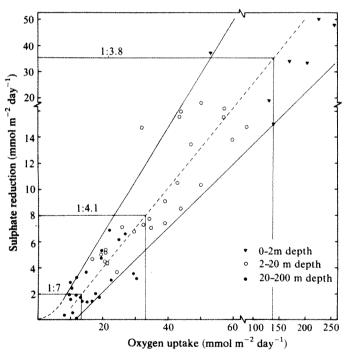

Fig. 1 Oxygen uptake and sulphate reduction rates (0-15 cm depth) of marine sediments from 0 to 200 m water depth in Kattegat, Skagerrak and Danish fjords. Sediments were carefully collected in 3-5 cm-wide coring tubes, which were kept at in situ temperatures under circulating, aerated water from the sampling locality and which preserved undisturbed the core stratification. Oxygen uptake was measured as the rate of disappearance of O2 from the water over stoppered sediment cores in the dark. Experiments were stopped after 10-20% O2 depletion to avoid decreasing uptake rates due to prolonged incubation. No bias in the O_2/SO_4^{2-} ratios due to pressure release is detectable for these sampling depths. The data are averages of cores for stirred and stagnant water columns. Sulphate reduction was measured by injecting 2 µl aliquots of ³⁵S-labelled sulphate into whole cores at 1-2 cm depth intervals. Labelled sulphide was analysed after a few hours' incubation. The vertical series of individual rates were integrated with depth to give the rate per area. Each data point represents 8-50 oxygen uptake and 20-100 sulphate reduction measurements per station. Details of the experimental techniques and of potential errors are discussed elsewhere'

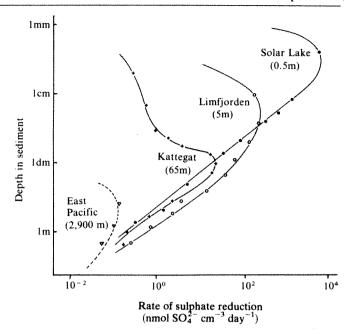

Fig. 2 Depth distribution of bacterial sulphate reduction rates for four sediment types. Water depths are indicated. Data are from Solar Lake¹⁴, Limfjorden⁶, Kattegat (B.B.J., unpublished results), and East Pacific¹⁵.

consumed by chemical or bacterial oxidation of the sulphide. The remaining 50% was used for respiration by the benthic fauna and by other aerobic organisms which use oxygen to oxidize directly the organic matter. In terms of oxidation of organic carbon, the contribution by the sulphate-reducing bacteria relative to the aerobic organisms was then $\sim 1:1$.

These conclusions generally hold for those sediments studied which have a community metabolism above $20\text{--}25 \text{ mmol } O_2 \text{m}^{-2} \text{ day}^{-1}$ (Fig. 1). Similar calculations made for sediments at 20--200 m water depth show an average O_2/SO_4^{2-} consumption ratio of 7:1 (Fig. 1). With 80% of the sulphide being re-oxidized by oxygen, $\sim 25\%$ of the oxygen uptake must have been consumed for H_2S oxidation. The mineralization of organic matter by sulphate reducers was thus equivalent to 35% of that directly mineralized by the aerobic organisms.

The relative importance of sulphate reduction in the shelf sediments investigated decreased with decreasing community metabolism and therefore with increasing water depth and distance from land. This may be explained by the fact that as the general metabolic rate of the sediments decreases the oxidized surface layer increases in thickness. The organic matter which reaches the deeper lying sulphide zone is therefore at a later stage of decomposition and relatively more refractory to further mineralization. The overall rate of mineralization which is expressed through the oxygen uptake consequently varies in direct proportion to the rate of organic sedimentation¹ whereas sulphate reduction varies rather in proportion to the square of the sedimentation rate 10,11. Once the organic matter has reached the sulphide zone, however, it has a long residence time and can sustain the low rate of sulphate reduction over great sediment depths. The range of sulphate reduction rates calculated per unit area of the sediment is therefore much less than the range of the peak rates. Figure 2 illustrates this trend in four sediment types which differ 100,000-fold in their peak rates of sulphate reduction. In the most dynamic sediment from a small salt pond in Sinai, Solar Lake, 90% of the entire sulphate reduction occurred within the uppermost 0.1-3 cm (ref. 14). With increasing water depth, the main activity was confined to deeper but thicker sediment layers of 1-10 cm in Limfjorden⁶ and 5-20 cm in Kattegat (B.B.J., unpublished results). In sediments of the East Pacific continental slope at 2,900 m water depth, sulphate reduction was traced from a few decimetres to several metres' depth¹⁵.

Sulphate reduction in the sea bed thus occurs mainly in the coastal zone. Shelf sediments, such as those studied here from the shoreline to 200 m depth, cover an area comprising only 8.6% of the world's ocean, but ≥90% of the oceanic sulphate reduction occurs here1:

The demonstrated importance of sulphate reduction in the overall mineralization of organic matter leads to a last essential point. The anaerobic bacterial food chain in which sulphate reduction is the terminal step, must be able to almost completely oxidize a wide range of organic compounds to CO2. Newly isolated strains of sulphate-reducing bacteria can oxidize all the major fermentation products (such as C-1-18 saturated fatty acids, lactate, ethanol, succinate, and benzoate, H2) completely to CO₂ and H₂O (ref. 16). Several of these strains have been found in high numbers in coastal marine sediments of the type studied here¹⁷. Furthermore, laboratory studies on similar sediments have shown that the lower fatty acids (acetate, propionate and butyrate) together with hydrogen³, are the main electron donors for the sulphate-reducing bacteria18. These results explain the discrepancy observed between the very restricted metabolic potential of sulphate-reducing bacteria which previously were known from marine environments (that is, Desulfovibrio spp.) and the evidence for an almost complete mineralization of organic matter via sulphate as demonstrated

New York 10024, USA

We report here that the first rodents from the early (or early middle) Miocene of North Africa have been found in the Rotem and Yeroham Basins in the northern Negev of Israel. The rodents are associated with a large-mammal fauna resembling those of Gebel Zelten (Libya) and Moghara Wadi and Siwa Oasis (Egypt). These are the earliest records of Miocene rodents north of the Sahara, and strongly support reconstructions of a drier, more open environment in the northern part of Africa compared with the equatorial regions, with obvious significance for the evolution of grassland-adapted faunas.

As a result of two seasons (1979-80) of collecting, fossil rodents, primates and carnivores have been recovered in a new site ('Anthracothere Hill') in the northern Negev of Israel

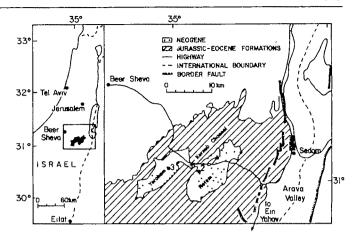

Fig. 1 Neogene basins of the northern Negev, Israel, -16-17 Myr (ref. 1).

(Fig. 1, site 1). Already these specimens have quadrupled the number of fossils known from the Negev; further study of Oron Road (site 2), which has been known for almost 30 yr, is just beginning.

Fossils of 'hippopotamus' and 'elephant' were first observed at Oron and Yeroham (site 3) during exploration for oil in the Negev during the 1950s². Savage and Tchernov³ identified these as an anthracothere and Mastodon (now Gomphotherium4) angustidens and Deinotherium bavaricum (now deinotherium hoblevi4), and also listed rhinocerotid, tragulid and hyaenodontid specimens. Stratigraphy of sites 2 and 3 was reviewed by Neev² and Savage³, sites 1 and 2 by Hoexter and Weinberger (in preparation) and sites 1-3 by J.A.V.C. Fossils from all three sites occur in basin-filling fluviatile deposits which have generally been correlated with the upper Mingar Member of the Hatseva Formation in the southern Jordan Rift Valley (Wadi Arava)⁵. We assume that deposition at these sites was approximately simultaneous, but because depositional environments are clearly different, the faunal lists are separated (Tables 1, 2).

In the Yeroham sites, specimens are found on the surface or in a poorly cemented, friable sandy matrix in low-relief badlands and gullies. An oyster reef (Crassostrea) 5 m above the mammalian fossils represents the maximum onlap of a marine transgression. The vertebrate fauna is depauperate, consisting of only four species (Table 1) represented by 22 specimens. Their size and shape appear to match the selection seen in Behrensmeyer-Voorhies Group III (ref. 6): a small collection of dense bones and teeth accumulated in a lag deposit.

At the Oron Road site, fossils occur just below the ground surface on the south-west-facing slope of the Rotem central arch, ~30 m south of the road. The matrix is indurated conglomerate with occasional pockets of quartzose sand. Clay balls, silt, flint cobbles and Cretaceous invertebrates from the flint occur rarely. Rare fragments of Crassostrea (Z. Lewy, personal communication) indicate either drainage from the Yeroham Basin, the reverse of early middle Miocene flow⁵, or the former presence of oyster reefs in eroded and redeposited parts of the Rotem sediments. Small fossils form 7% of a total of 73 specimens; no fish spines have been recovered. Large mammal bones and teeth were abraded in transport and subject to bioturbation,

desiccation and fracture *in situ*. The assemblage is Behrensmeyer-Voorhies I-II-III, redeposited after bulk transport in flood conditions⁶.

At Anthracothere Hill fossils occur on the steeply inclined eastern face of a low ridge, Giv'at Kadmai. A few large fossils, for example, a rhinoceros phalange and a palm stipe, were recovered in the slope wash. Strata underlying this ridge, not fully revealed, include 7-10 m mudstone; 1-1.5 m of fossiliferous, loosely indurated red-yellow quartzose sandstone and pebbly grit in 1-2-cm layers, interbedded with massive white sandstone; and 1-8 m of coarse sand, locally crossbedded; the ground surface is Cretaceous flint cobbles. Baculites, Ostrea, Dentalium and Exogyra fragments from Cretaceous flint are rare; chalcedony cobbles to 0.5 m, calcareous pebbles, limonite nodules, clay balls to 0.2 m and silt are randomly interspersed. Sand grain analyses and upward fining of the layers indicate a high-energy palaeoenvironment, such as a river bank or channel deposit.

Small fossils, including fish bones and spines, vertebrae and teeth of small mammals, are about one-third of 445 specimens from Anthracothere Hill (Table 2). Large bones, 10–20 cm, well preserved as to detail but not robust, such as a juvenile rhinoceros mandible, a bovid tibia and several ribs, were found encased in grit. These may have been scavenged or fresh carcasses cached by crocodiles or other predators⁶. The palate of a very young post-hatchling crocodile found within one such grit layer is consistent with underwater burial. Bone pebbles 0.2–10 cm occur, but overall the large numbers and well preserved aspect of the small fossils suggest Behrensmeyer-Voorhies class I–II and deposition after brief transport.

Vertebrate microfossils in fine white sand, a palm trunk and root casts have been found in Kurnub Channel, the Miocene channel between Rotem and Yeroham Basins (Fig. 1). A humerus of the Oligocene-Miocene dugongid Halitherium was recently found at Ein-Yahav in the Arava. In sum, despite variations in abrasion, taphonomy and stratigraphical context, it is probable that the fossils of Yeroham, Oron and Anthracothere Hill were deposited at more or less the same

time, perhaps within a few tens of thousands of years of one another. Although direct dating of the fossils has not yet been obtained, if the strata in these basins belong to the Hatseva Formation, they are older than the faulting that now separates the basins from the type area in the Jordan Rift; the age of this rifting has been estimated from fission-track analysis of the 'Mottled Zone' at 13.6 ± 2.0 Myr (refs 8, 9). On the other hand, the marine transgression and aggradational episode to which the Yeroham oyster reef may be related, may be either that of the late early Miocene 'Vindobonian transgression' associated with the guide fossils Orbulina and Borelis melo curdica at about 15-16 Myr, which in Israel was preceded by an erosional phase and followed by a desiccation event¹⁰, or the reef-building episode in the upper Ziqim Formation of late Miocene age, ~9 Myr (ref. 11). The mammal fauna, although not highly age-diagnostic in itself, seems clearly to be of earlier rather than later Miocene age³ and similar to later early Miocene faunas of Gebel Zelten, Wadi Moghara and Siwa Oasis, as is shown below.

Two taxa of 25, Dicerorhinus and Tomistoma, are found only at Oron; four taxa of 28, bird, insectivore, primate and cricedontid rodent, are found only at Anthracothere Hill, but these differences reflect sampling intensity and taphonomy. If palaeoecology can be inferred from similar modern forms^{12,13}, the combined inventory represents five habitats: brackish lagoon (dugong, sharks); river/lake/swamp (anthracothere, crocodiles, trionychid turtle, fish, palms); forest (testudinid turtle, tragulid, proboscideans, primate, creodont, carnivore); grassland (giraffid, bovid, rhino, creodont, carnivore, cricetid and pedetid rodents); and semi-arid to rocky landscape (gazelle, ctenodactylid rodent). Continued sampling may change these econiche estimates, but the impression is a large number of habitats confined in a small terrain, and lake basins draining a few hundreds of kilometres and debouching on to a coastal corridor.

The list contains 27 African endemic taxa and what appears to be an immigrant, the ctenodactylid *Metasayimys*, represented by 12 incisors from the Rotem sites. *Metasayimys* in the Rotem

sediments may be the earliest African appearance, if this fauna proves to correlate with MN zone 4 (ref. 14, see below). The next youngest record of this group is 'Ctenodactylid, sp. indet.' at Pasalar, Turkey¹⁵, in zone MN 5 and the equivalent, or slightly younger, Metasayimys cf. intermedius of the Dam Fm, As Sarrar, Saudi Arabia (H. Thomas, personal communication). Related species are *Metasayimys intermedius* Sen and Thomas 16 of the Hofuf Fm, Hasa Province, Arabia, "older than ... Beni Mellal (our translation)"; Metasayimys jebeli Lavocat17 of Beni Mellal, Morocco, and Sayimys from the Chinji Fm, lower Siwaliks, India 18,19, also about this age.

Hyoboops and Dicerorhinus have been considered slightly earlier immigrants from Asia, observed at Dera Bugti, Pakistan20-22, but as both appear at the approximately contemporaneous early Miocene sites in Kenya²³, an African origin seems equally probable. The creodonts and carnivores of Rotem-Yeroham (in preparation) also have African early Miocene affinities. African emigrants into Eurasia in the early Miocene are Dorcatherium, Gomphotherium, Prodeinotherium and Eotragus. Megapedetes, also emigrant, has been recovered at Bayraktepe, the southern Dardanelles, Turkey24, with a mix of faunal elements, some as young as ~13 Myr (for example,

To determine biogeographic correlation of the Negev fauna, we relied on radiometric- and marine-controlled dating of Rusinga²⁵, Europe^{14,26}, the Mediterranean²⁷ and a transect of the Israel shoreline 10. The major datum points are the Rusinga lavas at -18 Myr and the appearance of the foraminifer Orbulina suturalis at -16 Myr; Gebel Zelten is set at -16 Myr.

In Table 3, based on small-to-large herbivores, we equate the Negev basins and Gebel Zelten, Libya, and by extension, Moghara and Siwa, Egypt²⁸⁻³⁰. (Determination of the Rotem creodonts and carnivores may alter the estimate.) The Rotem-Yeroham assemblage seems to be slightly older than that of As Sarrar in western Arabia (H. Thomas, personal communication) and ranked by age, older than the fauna of Al Jadidah and Ab Dabtiyah, Saudi Arabia, the India-Pakistan sites, and Fort Ternan, Kenya, the last dated 14 Myr (refs 31-35). Hyoboops and Dicerorhinus suggest that Rotem-Yeroham is younger than Dera Bugti^{21,22} and Rusinga²³.

The best estimate for the Negev fauna is thus -16-17 Myr, a time of global warming and land emergence observed in the Mediterranean Sea and at continental margins 10,36,37. The thermal high that began in the earliest Miocene was just at peak and Israel shore emergence was maximal. Cogley's reconstruction of the eastern proto-Mediterranean -20 Myr (J. G. Cogley, personal communication) shows a filling-in between Israel and Turkey which agrees with the ctenodactylid appearance at Pasalar. Except for the faunal comparisons, however, the early middle Miocene has revealed no compelling geological evidence for a connection between Negev basins and Europe via Turkey.

Free Ca2+ and cytoplasmic streaming in the alga *Chara*

R. E. Williamson* & C. C. Ashley

University Laboratory of Physiology, Parks Road, Oxford OX1 3PT, UK

Plant cells, like those of animals, contain the Ca2+-binding protein calmodulin¹⁻⁴. By analogy with animal cells it has thus been suggested that the intracellular free Ca2+ concentration may have an important role in the regulation of plant cell activities. This suggestions has been supported by various physiological experiments, but so far direct evidence, invol ving measurements of intracellular Ca2+ levels, has not been obtained. We describe here measurements of intracellular Ca2 in the giant alga Chara by microinjection of the protein aequorin, which emits blue light in proportion to Ca2+ concentration. Chara exhibit an ATP-dependent cytoplasmic streaming shown to be inhibited by Ca^{2+} (refs 5, 6). We report that *Chara* cells have a low free Ca^{2+} concentration, comparable with those of animal cells, and that action potentials which inhibit cytoplasmic streaming⁷ increase this Ca²⁺ concentration substantially.

^{*}Present address: Department of Developmental Biology, Australian National University, PO Box 475, Canberra ACT, Australia 2601

Aequorin was injected into internodal cells of Chara corallina or Nitella sp., and initially showed a high light emission that, except for occasional transient increases, declined rapidly for 30-50 min (Fig. 1a). This probably reflected a relatively high cytoplasmic free Ca^{2+} concentration ($Ca_{\rm cyt}^{2+}$) as a result of the injection process, and precluded any detailed interpretation. In the next phase the light signal was low, subsequently declined very slowly and showed no transient increases in an undisturbed, undamaged cell (Fig. 1a). This is consistent with the injected aequorin now being evenly distributed by cytoplasmic streaming and with $Ca_{\rm cyt}^{2+}$ having declined to a low value, and this conclusion is supported by the finding that cells lysed in a solution containing a Ca^{2+} saturating for aequorin (solid line, Fig. 1b) contained active aequorin for up to 14.5 h after injection.

The peak lysis signal after correction for poor mixing $(L_{max}$ in saturating Ca^{2+}) and the *in vivo* aequorin signal (L) in Ca^{2+}_{cyt} were used to determine Ca^{2+}_{cyt} from a calibration curve relating L/L_{max} to free Ca^{2+} in vitro (Fig. 1b,c). The solutions used for this curve resembled characean cytoplasm in pH and free Mg^{2+} (Fig. 1c). Here two values for free Mg^{2+} were used because of the range reported for ATP, probably the major Mg^{2+} chelator. From the 3 mM free Mg^{2+} curve, the mean Ca^{2+}_{cyt} was found to be 0.22 μ M for Chara (range 0.1–0.56 μ M, n=6) and 1.1 μ M for Nitella (range 0.79–1.6 μ M, n=4). At 1 mM free Mg^{2+} , the mean values were lower, that is, 0.1 μ M and 0.44 μ M, respectively. Cells appeared undamaged by several physiological criteria and neither chloroplast light absorption nor partial aequorin inactivation by enzyme inhibitors generated at cell lysis introduced major inaccuracies into the estimates of Ca^{2+}_{cyt} . In addition, these values agree with those suggested by cell perfusion experiments 5.6.8.9.

Uncentrifuged cells were also injected with aequorin using a large tipped micropipette which penetrated the vacuole through ~10 μm of parietal cytoplasm¹0. The resulting relatively rapid light emission left little or no unreacted aequorir detectable on cell lysis after 15 min while unreacted aequorir was present 14.5 h after injection into the cytoplasmic compartment. The half time for aequorin utilization in a medium of sap expelled from cut cells indicated a near saturating Ca²-(L/L_max = 0.56). Any vacuolar inhibitors, including low vacuolar pH (Fig. 1 legend and ref. 11) will make this ar underestimate of vacuolar Ca²-, suggesting that the free Ca²- is >10⁻⁴ M in this compartment.

Thus characean cells contain a cytoplasmic compartmen where free Ca^{2+} is maintained at a concentration of micromolal or less and a vacuolar compartment where the free Ca^{2+} is $>10^{-4}\,\text{M}$. These measurements of free Ca^{2+} should be compared with measurements of total Ca^{2+} for characean cells indicating 3–12 mM in the vacuole 12–15 and 2–8 mM in the cytoplasm 6.15.

On electrical or mechanical stimulation, characean cells propagate action potentials along both the plasma and tonoplass membranes¹⁰ and this is associated with streaming cessation⁸. The ability of elevated Ca^{2+} concentration to inhibit both streaming in perfused characean cells^{5,6,16}, as well as chloroplass rotation in cytoplasmic fragments¹⁶ isolated from characean cells, makes a rise in Ca_{crt}^{2+} a likely explanation for streaming cessation by the action potential in intact cells⁸.

Chara cells with cytoplasmic aequorin were stimulated with external electrodes and changes in vacuolar potential (Ψ_{vo}) and either aequorin light emission or streaming velocity were measured. The electrical transient was accompanied by a large

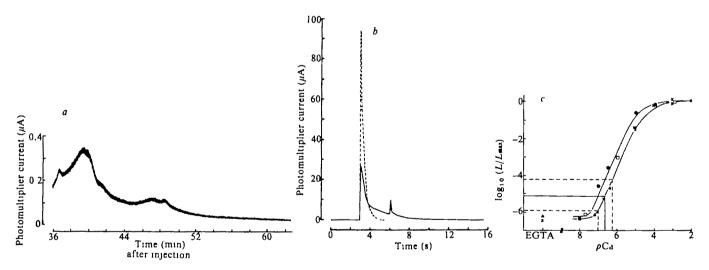

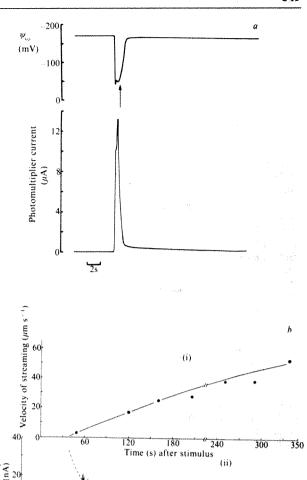

Fig. 1 Acquorin prepared as in ref. 35 was dissolved in (mM): 150 KCl, 10 N-tris(hydroxymethyl)methyl-2-aminoethane sulphonic acid (Na₂TES), pH 7.5, and ~50 nl (10% cytoplasmic vol) was injected into an internodal cell (~40 mm long) of Chara corallina or Nitella sp, which had been centrifuged at low speed for several minutes, and immersed, to reduce turgor, in (mM): 0.1 KCl, 1.0 NaCl, 200 or 250 sucrose, with the centrifugal end exposed. Acquorin was injected into the resulting endoplasm plug, the pipette withdrawn, and the cell returned to full turgor by diluting out sucrose with artificial pond water (APW) (mM): 0.1 KCl, 1.0 NaCl, 0.1 CaCl₂, 2 Na₂TES, pH 7.2). Acquorin light emission was detected with an EMI 9635A (~900 or ~1400 V) photomultiplier (signal output to a chart recorder via current-voltage convertor (RC = 200 ms or 0.1 ms) protected from amblent light by a shutter; (bar on time axes denotes shutter closure). All photomultiplier currents were standardized by conversion to their equivalent current at ~1,400 V with photomultiplier dark current (4.5 nA) and chamber ambient light (shutter open, unmjected cell, ~0.5 nA) subtracted. a, Acquorin light emission from cytoplasmically injected Chara cell. b, Light emission (solid line) following crushing of similar cell m a lyst solution (mM): 10 CaCl₂, 50 Na₂TES, 1% (v/v) Triton X-100, pH 7.3. Rapid, complete acquorin discharge required both crushing and detergent. L_{max} for Ca²/₂ calculation (ref. 45 and fig. 1c) requires correction for poor mixing as in the broken curve enclosing same area and with 1/1/2 = 0.49 s (1/2) measured in vitro when acquorin is rapidly mixed with lysis solution at ~20 °C (see ref. 35). c, In vitro cabbration curves for measuring Ch²/₂ tron L/L_{max} and L/L_{max} and Macla Ch²/₂ to 1.0 or 3 (×, A) free Mg²⁺, 30 Na₂TES, pH 7.6 and various Ca²⁺ concentrations achieved below 10⁻⁴ with EGTA. Mg²⁺ concentration approximated to cytoplasmic free Mg²⁺ calculated as total free Mg²⁺ (3.6 mM; ref. 5) minus

increase in light emission (Fig. 2a) which was not seen if uninjected cells were used. As in uninjected cells, the detailed shape of the electrical record varied from cell to cell, and to some extent with time in an individual cell, and the light emission varied similarly. Action potentials, which were all-ornone and typical of the characae, could be elicited repeatedly over several hours with only a gradual decline in the amplitude of the aequorin signal resulting from an estimated 4% of the aequorin being consumed by each action potential response (Fig. 2 legend). The peak light emission corresponds closely to the visually estimated time for streaming cessation (Fig. 2a; see also ref. 17). However, aequorin light returns to its resting level in 40-60 s, while streaming in different cells may take 75-360 s and have only reached some 25% of its full rate by the time aequorin light has fully recovered (Fig. 2b). If aequorin light accurately reflects changes in Ca_{cyt}²⁺, then a hypothesis of Ca²⁺ control requires a mechanism in which there is rapid inhibition by elevated Ca²⁺_{cyt} but slow recovery extending many seconds beyond the recovery time for Ca_{cyt}^{2+} . In vertebrate smooth muscle, where the time course of Ca_{cyt}^{2+} and tension also diverge¹⁸, free Ca²⁺ is thought to exert control via a calmodulindependent myosin light-chain kinase, causing phosphorylation which, in turn, is regulated by a cyclic AMP-dependent followed eventually by a slow dephosphorylation step¹⁹⁻²⁴. The existence of a similarly complex regulatory system in Chara may generate the substantial divergence observed between the recovery of streaming and of aequorin light.

We can also determine the magnitude of the free Ca2+ change as a result of the action potential. Ca2+ was calculated to rise 30-fold to 6.7 µM (mean of 6 cells) during a Chara action potential (from Fig. 1c taking $L \propto [Ca]^2$) (42-fold for Nitella to 43 μ M, n = 4). This would take Ca_{cyt}²⁺ into the range where ATP-dependent streaming in perfused cells is strongly inhibited by Ca²⁺ (refs 5, 6, 25) but it is still less than the 10⁻³ M Ca²⁺ needed to stop streaming completely in perfused cells⁸, as happens at the action potential¹⁷. This discrepancy implies (1) that there is another inhibitor of streaming associated with the action potential (perhaps, a change in cytoplasmic pH): (2) that the cell model is depleted by perfusion of some as yet uncharacterized regulatory protein, and is thus less sensitive to Ca2+ than the intact cell; or (3) that the peak Cacyt has been underestimated. This would occur if aequorin light emission were inhibited by, for example, a rise in the concentration of H⁺ or free Mg²⁺, if Ca²⁺_{cyt} did not increase in all parts of the cytoplasm, or if it increased asynchronously in different regions (see, however, Fig. 2 legend). The return of aequorin light to precisely its pre-stimulus value (Fig. 2b) indicates, however, that if any ionic changes affecting the sensitivity of aequorin occur, they must be short-lived.

Replacing external Ca2+ with Mg2+ leads to a reversible loss of excitability in Chara which may be due to a specific requirement for Ca²⁺ to initiate the transient change in anion permeability26. Mg2+ treatment of cells containing cytoplasmic aequorin led to partial depolarization and to a reversible decline in the magnitude of both the electrical and aequorin-light transients (Fig. 3a). This was accompanied by a loss of streaming inhibition which returned with the electrical and aequorin transients when Ca²⁺ was restored to the bathing solution. There appeared to be a degree of separation between changes in the electrical transient and the changes in the aequorin light response (Fig. 3a), with the alterations in electrical responsiveness preceding the changes in aequorin light emission during both the loss and recovery phases. The partial recovery of the electrical transient before the light transient is consistent with the idea that other ions^{14,26,27} besides Ca²⁺ have a role in the electrical transient besides Ca²⁺ have a role in the electrical transient. In Nitella, complete replacement of Ca2+ by Mg2+ results in no loss of excitability, a prolongation of the electrical response and no loss of streaming²⁸, suggesting that cytoplasmic Ca² stores are less likely to be a source of the changes in Ca_{cyt}²⁺: the results in Fig. 3a also support this notion, as do tracer influx experiments⁸

One batch of Nitella did not show the typical characean

Time (s) after stimulus

(iii)

Fig. 2 a, Changes in electrical potential (Ψ_{vo}) and aequorin light emission during an action potential. The 'tail' to the electrical record indicates that the electrode tip is in the vacuole10. Current pulses from a Devices Stimulator were applied to cell via full length external Ag/AgCl wire electrodes immersed in pools of APW, separated by a silicone grease barrier. The microelectrode signal was fed to a Keithley electrometer and then to a Tekman TE220 chart recorder. Either aequorin light emission, recorded from 90% of the cell length by a standard photomultiplier arrangement, or cytoplasmic streaming measured close to the microelectrode, were determined. Streaming cessation (determined visually) occurred ~300 ms after maximum depolarization (arrow). Calculations indicated that 3.7% (n=4) of the injected aequorin is consumed during each action potential. b, Recovery of aequorin light emission (ii) to pre-stimulus level following an action potential indicated on the record of vacuolar potential (Ψ_{vo}) (iii). (Output from photomultiplier was shorted out during the stimulus to show recording at high gain during the recovery phase). The photomultiplier current includes resting light from injected cell (~2 nA) (see Fig. 1 legend). (i) Indicates that the recovery of streaming velocity to its pre-stimulus value of $\sim 50~\mu m \, s^{-1}$ was much slower than recovery of the aequorin light emission. Observations are from the same cell. T, 20 °C. The cessation of chloroplast rotation at the action potential8 indicated that motility inhibition occurred at all depths in the endoplasm. However, the inhibition spreads radially inwards through the endoplasm at 15 μ m s⁻¹ so that, if the increase is being observed, all regions will be affected but not synchronously. Radial spread through a typical thickness of endoplasm would take ~0.5 s (ref. 10). However, the time between the stimulus artefact and the membrane response recorded at the further end of the cell suggest that the cell was excited almost simultaneously by the extensive external electrodes. While some asynchrony and therefore underestimation of the peak Ca_{ev}²⁺ seems possible, the consumption of only 4% of the total acquorin during each action potential severely restricts the time for which the 10⁻³ M Ca_{est}²⁺ required for complete inhibition in perfused cells could exist. As $t_{1/2}$ for aequorin reaction is ~ 0.5 s at 10^{-3} M Ca²⁺, 4% of the aequorin would be consumed in 40 ms if this concentration was reached instantaneously. If allowance is also made for acquorin consumption during the finite rising and recovery periods, the existence of 10^{-3} M Ca²⁺ would have to be even briefer.

Electrical potential (mV) Photomultiplier current

100 -50

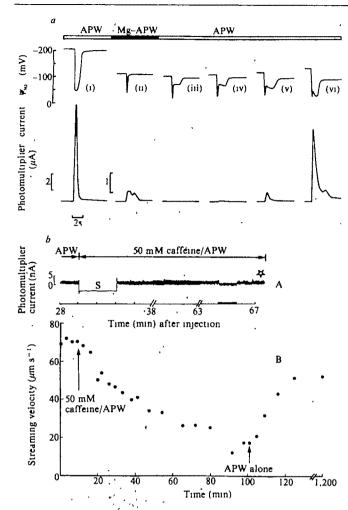

Fig. 3 a, Traces of vacuolar electrical potential (4,,) and aequorin light from Chara cell exposed for 26 min to Mg-APW (mM) 10 MgCl₂, 1 NaCl, 0.2 KCl, 2 Na TES, pH 7.2. Note that the electrical transient is preceded by a stimulus artefact clearly seen in trace (li) when the transient has been abolished. (ii) Mg-APW led to loss of electrical response and decline in acquorin light response that was complete by the time APW was restored (trace (iii)) Recovery of the electrical and aequorin light response (traces iii-vi) documented 13, 15, 24 and 40 mm after return of APW showed recovery of the aequorin light response to be slower than the electrical response as substantial electrical transients were observed in APW before a significant recovery of aequorin light response. Inhibition of streaming on stimulation was lost in Mg-APW, returning only slowly in APW. After 24 mm APW (trace v) there was no inhibition 30 s after stimulation, after 50 min in APW, streaming inhibition was complete (trace very similar to trace vi) but recovery was more rapid than normal (~75 s, see Fig. 2b) b, Inhibition of cytoplasmic streaming (B) in Nitella by 50 mM caffeine-APW was accompanied by no appreciable increase in acquorin light emission (A). The streaming record is from an uninjected cell but examination of the injected cell at the end of the light emission trace (4) revealed inhibited streaming which recovered on replacing the caffeine with APW. The artefact (S) on trace A represents a solution change with the photomultiplier output shorted out.

all-or-none behaviour¹⁰. Here stimuli of increasing magnitude evoked aequorin light transients of increasing size and resulted in correspondingly more marked inhibitions of cytoplasmic streaming^{29,30}. These results suggest that cytoplasmic streaming responds to Ca²⁺_{crt} levels intermediate between those found in the resting cell and those achieved at the normal action potential, behaviour which is qualitatively consistent with the response of perfused cells to such variations in free Ca²⁺ (refs 5, 6, 25).

Finally, Nitella cells were exposed to caffeine, which in muscle is able to release Ca²⁺ from the sarcoplasmic reticulum and cause contraction³¹. In plants, caffeine inhibits cytokinesis³², vesicle secretion³³ and chloroplast rotation³⁴. Caffeine inhibited cytoplasmic streaming in Nitella (Fig. 3b), although only at the rather high concentrations needed to stop chloroplast rotation in Coleochaete³⁴. However, the inhibition of streaming in Nitella

was not accompanied by any substantial increase in aequorin light emission (Fig. 3b). Thus caffeine inhibits a Ca² plant process, but apparently not by appreciably increasing

Ca_{cyt}²⁺ in the two characean algae studied is some 10⁴ times lower than total cytoplasmic Ca²⁺. While clearly an extrapolation, it seems likely that all plant cells will conform to this low Ca²⁺ pattern as have the diverse animal cells studied to date³⁵.

Given these low Ca²⁺ values, the external 10⁻⁴ M Ca²⁺ and 10⁻⁴ M Ca²⁺ in the vacuole provide large electrochemical gradients for Ca²⁺ entry into the cytoplasm at both the plasma membrane (cytoplasm ~170 mV negative) and the tonoplast (cytoplasm ~20 mV negative¹⁰). Although the measured Ca²⁺ influx at the plasma membrane is small ($\sim 0.04~\mathrm{pmol~cm^{-2}~s^{-1}})^{8.13}$, in isolation this would raise $\mathrm{Ca_{cyt}^{2+}}$ at the rate of $0.04~\mu\mathrm{M~s^{-1}}$, a large change in relation to the resting Ca²⁺; this calculation assumes a 10 μm-thick layer of cytoplasm and no binding or sequestration. Our results indicate that sequestering by cytoplasmic organelles may provide short-term control of Ca²⁺_{cyt}. Long-term stability would require Ca²⁺ movement either directly out of the cytoplasm across the plasma membrane or into the large vacuolar reservoir, presumably ultimately effluxing to the external medium; a flux of $0.04 \text{ pmol cm}^{-2} \text{ s}^{-1}$ would increase the total Ca²⁺ by ~1 mM in 7 h. In a situation where several organelles plus the plasma membrane and tonoplast may contribute to maintaining Ca²⁺_{cyt} the quantitative importance of each component process in vivo is at present difficult to predict.

The range of Ca²⁺_{crt} changes reported here corresponds well to the operating range for calmodulin and other Ca2+-regulated proteins⁵⁰ and suggests that changes in Ca²⁺_{crt} could regulate, either directly or indirectly, many aspects of plant cell biology. So far the action potential is the only proven effector of a change in plant Ca_{cyt}^{2+} and it remains to be determined whether action potentials in other plant cells^{36,37} use Ca_{cyt}^{2+} to exert their postulated effects on processes such as morphogenesis 38,39 Similarly, cytoplasmic streaming is the only physiological process known to be affected by that Ca²⁺_{cyt} change, although other Ca²⁺ effects have been postulated for characean cells, such as the possibility that light and plant hormones are also able to change Ca_{cyt} (Refs 40-44). It is now possible with this method to investigate these suggestions more precisely.

Non-coated membrane invaginations are involved in binding and internalization of cholera and tetanus toxins

R. Montesano, J. Roth, A. Robert & L. Orci

Institute of Histology and Embryology, University of Geneva Medical School, CH-1211 Geneva 4, Switzerland

The binding of various biologically significant macromolecules to specific cell surface receptors is followed by their internalization, a process called receptor-mediated endocytosis1... In most cases, it has been shown that receptor-bound ligands cluster in characteristic, bristle-coated indentations of the cell surface known as coated pits1-3. In addition to coated pits, cultured cells have a population of smaller, non-coated membrane invaginations⁴⁻⁶, which may have a role in endocytosis^{2.7}. However, no receptor-bound biologically active ligand has been shown to enter cells via these non-coated invaginations. The studies implicating coated pits in receptor-mediated endocytosis concern essentially ligands that bind to receptors thought to be glycoproteins. We have therefore investigated by electron microscopy the endocytosis of cholera toxin and tetanus toxin, ligands which bind to membrane glycolipids, in particular to either GM₁ monosialoganglioside⁸⁻¹¹ or di- and trisialogangliosides12-15 respectively. We show here that in cultured liver cells, non-coated membrane microinvaginations are preferentially involved in both the initial binding and subsequent internalization of colloidal gold-labelled cholera and tetanus toxin.

The rat liver cell line KLTRYPV16 (provided by Dr G. Vergani) was maintained in monolayer culture as described elsewhere17. The cells were incubated with gold-labelled toxins as described in Fig. 1 legend, then washed three times with ice-cold phosphate-buffered saline (PBS) and either immediately fixed at 2 °C in 2% glutaraldehyde in PBS for 15 min, or warmed to 37 °C for 10 or 30 min before fixation. The cultures were further processed in situ for electron microscopy, as described previously18

The distribution of cholera toxin-gold and tetanus toxin-gold complexes at 2 °C on thin sections cut perpendicularly to the plane of the monolayer was essentially similar. Gold particles were scattered at irregular intervals along the plasma membrane, including the microvilli, but were frequently associated with non-coated, flask-shaped microinvaginations (Fig. 1a, b). In contrast, coated pits were labelled only very rarely. The association of toxin-gold complexes with the small, non-coated invaginations was also apparent in sections parallel to the substratum, in regions where the membrane had been cut tangentially (Fig. 1c, d). To check the specificity of labelling, cells

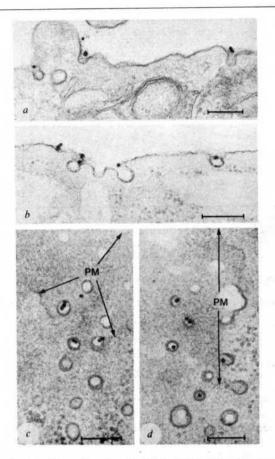

Fig. 1 Labelling pattern in cultured liver cells exposed to cholera toxin-gold (a, c) or tetanus toxin-gold (b, d) complexes at 2 °C. The preferential labelling of non-coated, flask-shaped microinvaginations is evident in sections cut either perpendicularly (a, b) or tangentially (c, d) to the plasma membrane (PM). As seen in a and b, gold particles are mostly located at the neck of the microinvaginations in these conditions. Colloidal gold (particle diameter ~15 nm) was prepared according to Frens²⁸ and the pH adjusted to 6.9 with 0.2 M K2CO3. Cholera toxin (Schwarz/Mann, New York) and tetanus toxin (given by Dr B. Bizzinni) were brought to 5 mM NaCl by passage through a Sephadex G-25 column (0.9 × 10 cm) equilibrated and eluted with 5 mM NaCl. The minimum amount of cholera toxin or tetanus toxin needed to stabilize a given volume of colloidal gold was estimated according to Roth and Binder²⁹. The crude toxin-colloidal gold preparations were centrifuged at 60,000g at 4 °C for 1 h and resuspended in phosphate-buffered (50 mM, pH 7.4) isotonic saline to a final concentration of 100 µg cholera toxin per ml or 1 mg tetanus toxin per ml. Cells grown to confluency in Linbro multi-well plates (Flow) were washed three times with ice-cold PBS and equilibrated at 2 °C for 5 min before incubation with cholera toxin-gold or tetanus toxin-gold at 2 °C for 30 min. Scale bar, 0.2 μm.

were first incubated at 2 °C for 30 min with either unlabelled cholera toxin (500 µg ml⁻¹) or tetanus toxin (2.5 mg ml⁻¹) in PBS, then exposed to the toxin-gold complexes. In such conditions, surface labelling was virtually absent.

In liver cells warmed to 37 °C for 10 or 30 min before fixation, gold particles were found in small non-coated cytoplasmic vesicles (Fig. 2a), in larger vacuoles having the morphology of multivesicular bodies (Fig. 2b) and in typical lysosomes. Coated pits or vesicles were only rarely labelled. To ensure that coated pits were functional in these cells, experiments similar to those described above were done after indirect labelling of concanavalin A (Con A) binding sites with Con A followed by horseradish peroxidase (HRP)-gold¹⁹. Labelling of coated pits and vesicles was commonly observed with this ligand (data not shown).

The distribution of cholera and tetanus toxin surface labelling was quantified by calculating the ratio between the percentage of gold particles bound to each membrane specialization and

Table 1 Association of cholera toxin-coated gold particles with cell surface features

Cell surface feature	% Gold particles associated with the feature	% Surface length occupied by the feature	Ratio
Flat plasma membrane	34.1	55.5	0.6
Microvilli	30.1	34.5	0.9
Smooth microinvaginations	35.8	8.9	4.0
Coated pits	0	1.1	0

The numbers of gold particles found on flat regions of plasma membrane, microvilli, smooth microinvaginations and coated pits on the apical cell surface were counted directly in the electron microscope on sections cut perpendicularly to the substratum. In each case, 35-50 cells (~1.0-1.7 mm of cell surface) were evaluated. Each cell was then photographed and the length of the whole apical cell surface and the length of each surface feature were measured on negatives projected at an appropriate magnification (×46,000 for flat membrane and microvilli; ×92,000 for smooth and coated invaginations) on a graphic tablet connected to an IMSAI microprocessor. The relationship of cholera toxin-coated gold particles to the various features of the cell surface at 2 °C is expressed as the ratio between the percentage of particles associated with a given feature and the percentage of the length of the cell surface occupied by the feature. A ratio of ~1 means that labelling is random. A ratio <1 suggests an exclusion; a ratio >1 indicates a preferential association.

the per cent length of cell surface occupied by that structure. The only preferential binding (with a ratio of 4) of gold-labelled cholera toxin at 2 °C was to the non-coated small membrane invaginations (Table 1). For tetanus toxin, we found a similar but less pronounced initial preferential binding (ratio of 1.5) to non-coated membrane invaginations (see Fig. 3). Furthermore, our qualitative observation that in cells incubated at 2 °C the neck of the flask-shaped membrane invaginations was more frequently labelled than the body region (compare Fig. 1a, b) was confirmed quantitatively (Fig. 3). In view of the rigidity of the membrane at 2 °C, this phenomenon could result from an impaired transfer of the gold tracer into the body of the invaginations. In contrast, after 10 min, and more markedly after 30 min of warming to 37 °C, gold particles were preferentially associated with the body of the smooth microinvaginations; the association of the label with microinvaginations as a whole was also more pronounced than at 2 °C. Cholera toxin surface labelling was reduced by only 1% after 10 min of reincubation to 37 °C, and by 26% after 30 min, indicating a slow rate of internalization. The decrease of surface labelling at 37 °C was more rapid in the case of tetanus toxin (34% after 10 min, 77% after 30 min).

In conclusion, our results show that: (1) at 2 °C toxin-gold complexes bind preferentially to non-coated, flask-shaped microinvaginations; (2) this preferential association becomes more pronounced after warming of the cell to 37 °C and is accompanied by a progressive translocation of the label from the neck to the body of the invaginations; and (3) at 37 °C the label is internalized via small, non-coated vesicles, probably derived from the surface microinvaginations, and accumulates in multivesicular bodies and lysosomes. We cannot, however, exclude the possibility that a small fraction of the label may enter cells through coated pits in the first few minutes after warming to 37 °C, as we did not study time points earlier than 10 min.

Studies on a variety of systems have contributed to the now widely accepted view that receptor-mediated endocytosis proceeds through clathrin-coated pits on the cell surface¹⁻³. These studies concern essentially ligands that bind to membrane receptors thought to be glycoproteins¹⁻³. However glycolipids, and in particular gangliosides, can also serve as selective receptor sites for various macromolecules²⁰⁻²², including cholera⁸⁻¹¹

and tetanus12-15 toxins, but the surface events involved in the internalization of these ligands have received only limited attention²³⁻²⁵. Joseph et al.²⁴ mentioned that cytoplasmic coated vesicles did not participate in the internalization of peroxidaselabelled cholera toxin by neuroblastoma cells. However, their study focused on late events of internalization and the type of surface invagination involved in the early stages of endocytosis was not investigated. The present results demonstrate that both the initial binding and subsequent internalization of goldlabelled cholera and tetanus toxin are mediated by non-coated surface microinvaginations, which suggests that the pathway of endocytosis of a ligand may depend on the chemical nature of its receptor. In this respect, it is interesting that gangliosides, due to their localization in the outer leaflet of the membrane bilayer, may not interact directly with the clathrin coat on the cytoplasmic side of the membrane. The present observations are also consistent with the notion that coated pits may act as molecular filters^{3,26}, concentrating some specific membrane components^{1,6}, but excluding others^{18,26}. The exclusion of gangliosides, in particular, could correlate well with the reported absence of sialic acid groups from coated pits27

In conclusion, our observations together with the previous studies on antibody-induced endocytosis of HLA antigens⁷ strongly suggest that there are at least two distinct pathways

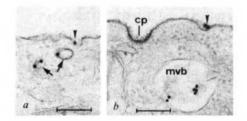

Fig. 2 Internalization of tetanus toxin-gold by cultured liver cells during reincubation at 37 °C for 30 min. Gold particles are present in smooth microinvaginations (arrowheads), in small non-coated cytoplasmic vesicles (arrows) and in a multivesicular body (mvb). There is no labelling of a coated pit (cp). Scale bar, 0.2 μm.

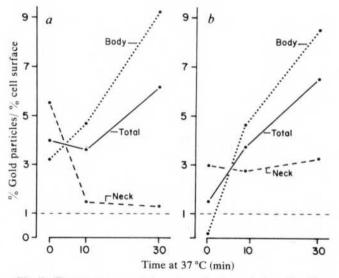

Fig. 3 Temperature- and time-dependent association of gold-labelled cholera (a) and tetanus (b) toxins with non-coated membrane microinvaginations. The time point '0' refers to cells fixed immediately after incubation at 2 °C. The ratio as defined in Table 1 was estimated for the microinvaginations as a whole, and also separately for the neck and body regions. The neck was defined as the region of membrane running from the most constricted part of the invagination up to the flat surface of the plasma membrane, and the body was the portion below the constriction. The neck was found to correspond to 3.4% of the total cell surface length and the body to 5.5%.

for internalization of surface-bound ligands, one involving coated pits and the other involving non-coated microinvaginations.

Conversion of a gonadotropin-releasing hormone antagonist to an agonist

P. Michael Conn*, Deloris C. Rogers*, John M. Stewart[†], James Niedel[‡] & Timothy Sheffield*

* Department of Pharmacology and ‡ Department of Medicine. Duke University Medical Center, Durham, North Carolina 27710, USA

† Department of Biochemistry, School of Medicine, University of Colorado, 4200 East Ninth Avenue, Denver, Colorado 80220, USA

Gonadotropin-releasing hormone (pyroGlu¹-His²-Trp³-Ser⁴-Tyr5-Gly6-Leu7-Arg8-Pro9-Gly10 amide, GnRH) stimulates pltuitary luteinizing hormone (LH) release. An antagonist, D-pyroGlu¹-D-Phe²-D-Trp³-D-Lys⁶-GnRH (GnRH-Ant), binds to the pituitary GnRH receptor and inhibits GnRHstimulated (10^{-9} M) gonadotropin release from pituitary cultures $(IC_{50} = 2 \times 10^{\times 7} \text{ M})$. GnRH-Ant has no measurable agonist activity at concentrations up to 10^{-6} M. The presence of the D-Lys6 both affords protection against proteolysis and includes an amino group which may be used for derivatization without loss of receptor-binding activity. Formation of the GnRH-Ant dimer by cross-linking of the (lysyl) amino groups of two molecules with ethylene glycol bis(succinimidyl succinate) (EGS) results in a GnRH-Ant dimer joined by a 12-15 Å chain. As the amino terminus on GnRH-Ant is blocked, leaving the D-Lys6 amino group the only reactive group1, the reaction of EGS with GnRH-Ant does not lead to larger polymers. Like the parent compound, this dimer is purely an antagonist. We now show, however, that when antibody (AB) to D-Lys6-GnRH (which cross-reacts with GnRH-Ant) is incubated with excess dimer, a product is formed which consists of a divalent antibody with a GnRH-Ant dimer attached to each arm: AB-((GnRH-Ant)-EGS-(GnRH-Ant))2. In contrast to the parent compounds, this conjugate is an agonist, stimulating LH release from pituitary cultures. Our results suggest that a pure antagonist becomes an agonist when it is capable of bringing two molecules within critical distance, (15 Å < d < 150 Å). The data indicate that formation of the receptor microaggregate itself is sufficient to stimulate a transmembrane response system.

Figure 1 shows the ability of GnRH-Ant to inhibit GnRHstimulated LH release from pituitary cell cultures. GnRH-Ant was an effective inhibitor of stimulated LH release; alone it has no detectable agonist action at concentrations up to 10⁻⁶ M. Figure 2 shows the elution pattern (G-25 column chromatography) of (1) authentic 125 I-GnRH-Ant, (2) EGS+GnRH-Ant dimerization reaction mix and (3) the EGS+GnRH-Ant dimerization mix in which the cross-linking volume was 10 times greater than in (2). Although complete separation of the monomer and dimer was not possible, the leading edge (see bracket in Fig. 2) consisted of fractions of GnRH-Ant dimer which contained <0.5% monomer. To provide evidence for the formation of a dimer, EGS cross-linking was performed in a 10-fold greater than normal incubation volume (a condition which would not favour the two second-order reactions required for the formation of the GnRH-Ant dimer). This resulted in an elution pattern in which a smaller percentage of the total GnRH-Ant was cross-linked by EGS.

We next analysed the activity of AB-((GnRH-Ant)-EGS-(GnRH-Ant))₂. In this conjugate, one molecule of each GnRH-Ant dimer is attached to each antigenic binding site and is therefore unavailable to the receptor. The other molecule of each dimer is available to the receptor, although it is bound to

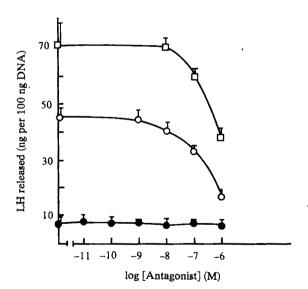

Fig. 1 Antagonist activity of GnRH-Ant in the cell culture bloassay: 2-day pituitary cell cultures² were incubated with 10^{-8} M (\Box) , 10^{-9} M (\bigcirc) , or no (\bullet) GnRH at the indicated concentration of antagonist. After 5 h incubation, the medium was assayed for LH by radioimmunoassay (RIA) using rat anti-LH antisera (LHS-4), highly purified rat LH for labelling (LH-I-4) and rat LH standard (LH-RP-1), which were made available by a grant from the NIAMDD Hormone Distribution Office (prepared by Dr A. Parlow). The assay was performed as previously reported², except that a second antibody was used to separate the bound and free ¹²⁵I-LH. The intra-assay variance was 7% and the inter-assay variance 12%. As indicated, LH release was normalized for slight differences in cell numbers in different wells by DNA determination 15.

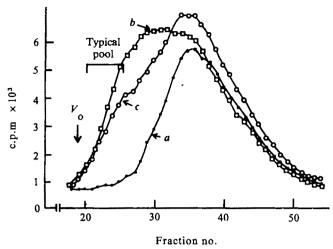

Fig. 2 Elution profiles of 125-I-GnRH-Ant (a), the EGS-GnRH-Ant-containing dimerization reaction mixture (showing a typical pool of the purified dimer (b) and the identical reaction conducted in a 10-fold greater volume (c). GnRH-Ant (prepared by J.M.S., batch LR307/29-39) was iodinated using chloramine T I and unlabelled hormone were removed from the GnRH-Ant by CM-cellulose column chromatography, as described previously except that the labelled analogue was eluted from the column with 200 mM sodium phosphate, pH 4.5. Maximum binding (assessed by binding with excess GnRH antiserum (no. 9113), prepared and used as in ref. 7) ranged from 89 to 92% in different preparations and specific activity (assessed by self-displacement assay with pituitary plasma membrane fragments 17) was $\sim 1~\text{mCi}~\mu\text{g}^{-1}$. The product was stored in the elution buffer at 4 °C for up to 2 weeks. At that time, >90% of the hormone (in different preparations) was intact as judged by electrophoresis¹⁷. Ten nmol of GnRH-Ant in . Ten nmol of GnRH-Ant in 10 μ l of 10 mM sodium phosphate, pH 8.5, and 20 μ l (~0.05–0.15 μ Ci) of ¹²⁵I-GnRH-Ant in 200 mM sodium phosphate, pH 8.7, were combined with 5 nmol of EGS (Pierce Chemical, Illinois) in 1.5 µl of dimethyl sulphoxide (DMSO, redistilled from Fisher). The EGS was stored in the dark at -70 °C and was dissolved in DMSO immediately before use. As EGS has 2 mol of reactive groups per mol, the reactive groups were present in equimolar concentration with the lysyl e-amino in GnRH-Ant. After 1 h at 18 °C, the reaction was terminated by dilution with 270 µl 40% ethanol, 10 mM sodium phosphate, pH 8.5, and immediately applied to a G-25 column (10×260 mm) previously equilibrated in the ethanolic buffer. Positions of cluting substances were determined by radioactivity and confirmed by RIA (using antibody 9113 at final titre of 1:7,000, radioiodinated GnRH and authentic GnRH-Ant standard).

the antibody via the 15 Å chain and the other molecule of GnRH-Ant. The product thus consists of two molecules of GnRH-Ant available to the receptor although separated from each other by ~150 Å. Figure 3 shows the ability of column fractions containing AB-((GnRH-Ant)-EGS-(GnRH-Ant))2 (the 'conjugate' which elutes in the V_0) to stimulate LH release from pituitary cultures. In contrast to GnRH-Ant alone, the conjugate displayed agonist action, evoking release of 9 ± 1.0 ng LH per 20 µl of medium compared with 0.8±0.1 ng LH per 20 μ l medium for basal release and 13.6 \pm 0.9 ng LH per 20 μ l of medium released in response to 10⁻⁷ M GnRH during a 5 h period. Stimulated release was blocked by 2 mM EGTA (in the presence of 'normal' 1.25 mM extracellular Ca2+) and by 5 µM Pimozide (which behaves as a calmodulin antagonist in this system²). In addition, neither the antibody alone (Fig. 3) nor the GnRH-Ant dimer alone stimulated measurable release (0.9± 0.1 ng LH per 20 µl medium). The reduced pepsin AB fragment (monovalent AB) conjugated with GnRH-Ant dimer did not stimulate release, indicating the requirement for bivalency to produce this effect.

GnRH occupancy of its receptor stimulates pituitary gonadotropin release by a calcium-mediated mechanism³ involving calmodulin^{2,4}. Occupancy leads to patching, capping and internalization⁵, although neither internalization of the releasing hormone nor large-scale patching and capping of the hormone-receptor complex are required for stimulation of LH release^{6,7}. The results reported here support the view that formation of a microaggregate of the GnRH receptor is sufficient to transduce the signal across the plasma membrane and to elicit cell responses if the separation distance between ligands is increased to a critical point. Thus, although both agonists and antagonists may bind to similar sites on the receptor, the latter is unable to produce the active functional unit. The GnRH-Ant dimer possesses only a 15 Å separation which appears to be inadequate to bridge receptor binding sites; so it cannot stimulate release. The added length due to the antibody indicates that the 'correct' bridge length is ~150 Å.

It is unlikely that the releasing hormone itself bridges two receptors because it is neither multivalent nor sufficiently long. A more likely possibility is that receptor occupancy by an agonist alters the receptor structure so as to increase the probability of microaggregation. For example, occupancy (by an agonist) might increase mobility of the receptor in the plasma

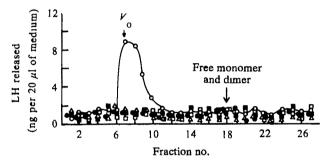

Fig. 3 Effect of column fractions containing AB-dimer conjugate on LH release from pituitary cell cultures. 120-160 ng (GnRH-Ant)2-EGS collected from the leading edge of the G-25 ∞lumn described for Fig. 2 (which contained <0.5% of the free GnRH-Ant, or EGS-GnRH-Ant monomer complex, estimated from other column eluant patterns) were lyophilized in a glass tube. Rabbit anti-D-Lys⁶-GnRH (antiserum no. 5111 prepared by immunization with D-Lys⁶ coupled to bovine serum albumin (BSA) with glutaraldehyde) was added without additional purification in an amount sufficient to bind 8-10% of the dimer. The AB was added in a final volume of 50 µl (with Medium 199 containing 0.3% BSA and 2 mg NaN3). The reaction was carried out for 10 h at room temperature and then for 2 days at 10 °C. Immediately before the cell bioassay, the solution was applied to a 12 ml calibrated G-75 column (10×260 mm) equilibrated in Medium 199/BSA. Twenty drop fractions (~300 µl) were collected and brought to 1.0 ml with Medium 199/BSA. The conjugate elutes in the V_0 . Where monovalent antibody is specified, the reduced 18 pepsin fragment 19 of antibody 5111 was substituted for intact antibody in the conjugation described above. In this case ammonium sulphate-fractionated IgG was dissolved in 50 mM acetate buffer, pH 4.5, and digested with pepsin (Worthington Biochemical) at an enzyme/substrate ratio of 1:100 at 70 °C for 50 min. Digestion was stopped by neutralization with 1 M Tris-HCl, pH 8.0 and 0.1 M NaOH. Precipitated material was removed by centrifugation and 2-mercaptoethanol was added to the supernatant at a final concentration of 0.75 mM. The solution was maintained at room temperature for 1 h, then cooled in ice-cold water. An equal volume of 0.75 mM iodoacetamide (previously degassed and cooled at 4 °C) was added and triethanolamine added to maintain the pH at 8.0 ± 0.2 . After 1 h the solution was dialysed against three (2 h each) 100 vol changes of 0.9% NaCl then lyophilized. This product was >95% cleaved as judged by the inability to precipitate ¹²⁵I-D-Lys⁶-GnRH with protein A. Cell cultures (described in Fig. 1 legend) were incubated with the aliquots from the column fractions in a final volume of 1.0 ml of Medium 199 containing 0.3% BSA. The conjugate $(n = 7, \bigcirc)$ stimulates LH release (by RIA as described for Fig. 1) which is blocked in the presence of 10 μ M Pimozide ($n = 3, \triangle$), or 2 mM EGTA $(n=3, \blacksquare)$. A conjugate prepared with monovalent antibody $(n=3, \Box)$ or bivalent antibody alone $(n=3, \bullet)$ did not stimulate release. Standard errors of the means, which are not shown for clarity, were <15% of the indicated value.

membrane by releasing it from anchoring; alternatively, a conformational change might occur such that complementary binding sites are exposed. It is also possible that occupancy activates enzymes which catalyse the formation of disulphide8 or peptide9 bonds and thereby link receptors. An antagonist would be viewed as occupying the binding site without effecting these changes.

Microaggregation of plasma membrane receptors seems to be required for the activation of some other plasma membraneregulated systems. In the case of epidermal growth factor (EGF)-stimulated mitogenesis in 3T3 fibroblasts 10, , cyanogen bromide treatment of EGF results in a molecule (CN-EGF) which binds to the EGF receptor but does not elicit mitogenesis. Addition of bivalent EGF antibody, which presumably brings together the occupied receptors, results in activation of mitogenesis. Further, anti-insulin receptor antibodies can stimulate insulin-like functions in target tissues¹¹. Bivalent antibodies are required for this stimulation¹², indicating the importance of a receptor microaggregation in this process also.

Divalent antigens such as EGS-(GnRH-Ant)₂ have been useful in the determination of the bridge length between the binding sites on antibodies¹³ and in the demonstration of the bivalency of IgG molecules¹⁴. The technique described here provides a general means of preparing a bivalent antibody that binds to the active site of a receptor from an antibody which was initially prepared by immunization with the ligand.

The work was supported by the Mellon Foundation through the Ford-Rockefeller Mellon Program for Targeted Research in Reproduction and by NIH grant HD 13220. P.M.C. is the recipient of grant RCDA HD 00337 and a senior fellow in the Center for the Study of Aging and Human Development. We thank Drs J. Blum, N. Kirshner, S. Pizzo and T. Slotkin for commenting on the manuscript, and Dr M. Karten of the Contraceptive Development Branch (NIH) for helping to locate the antagonist used in this study.

Axon segments sprout at both ends: tracking growth with fluorescent D-peptides

Adrian Mason & Kenneth J. Muller

Department of Embryology, Carnegie Institution of Washington, 115 West University Parkway, Baltimore, Maryland 21210, USA

In the nervous systems of many animals, including vertebrates, isolated axon segments can survive for weeks or even months 1they can participate in regeneration^{4,5} and in some cases receive synapses from regenerating axons^{6,7}. Axon segments in cell culture exhibit limited growth⁸⁻¹⁰. Although lengths of axon may grow in more intact systems¹¹⁻¹⁴, direct evidence for this has been difficult to obtain, partly because of the difficulty of marking isolated axon segments. We have injected fluorescently labelled synthetic D-peptides¹⁸ into identified neurones in the leech central nervous system to mark axon segments. We report here that individual segments can initiate growth at both ends and grow for days, both in organ culture and in vivo. These results support the hypothesis that axon growth is not essentially polar and suggest a novel mechanism by which axon segments may assist nerve regeneration.

Cell bodies of pressure (P) sensory neurones¹⁶ were injected with either rhodamine- or fluorescein-conjugated D-peptide15 which spread throughout the cell (see Fig. 1 legend). The synthetic peptide consists of 12 amino acids in the D-configuration, making it resistant to proteolytic enzymes¹⁵. Two days after injection into cells within cultured chains of ganglia, axon segments 2-4 mm long were produced by crushing or cutting the nerve cord at two sites between adjacent ganglia (Fig. 1). Growth was traced at 1- or 2-day intervals by viewing the preparation with an image-intensified camera and epifluor-escent illumination¹⁷ (Fig. 2). At the end of the experiment, preparations were fixed and viewed by conventional fluorescence microscopy (Fig. 3).

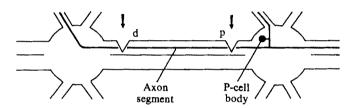

Fig. 1 A schematic diagram of the nerve cord preparation. P-cell bodies were pressure-injected using glass microelectrodes filled with either rhodamine-D-peptide (2% in 0.2 M KCl with 0.2% Fast Green FCF) or fluorescein-D-peptide (2% in 0.025 M Trischloride buffer pH 11, with 0.2% Fast Green FCF and 0.1 M KCl). Injections were performed in chains of ganglia pinned to silicone rubber (Sylgard 184, Dow Corning) and maintained in supplemented Leibowitz-15 culture medium 19,30. After 2 days, the nerve cord was cut or crushed in two places (arrows) between adjacent ganglia, creating an axon segment with proximal (p) and distal (d)

Axon segments began sprouting within the first day after cutting and continued to grow for at least 6 days (Fig. 2). After longer periods, increased background autofluorescence at the lesion site made it difficult to detect fine branches (or neurites). Typically, fine sprouts emerged from the ends of the severed axon, and branched and grew in several directions within the nerve cord, including backwards along the axon (Fig. 3). Some neurites had at their tips a swelling which seemed to be a growth cone, and small swellings or varicosities were seen at points along the sprouts, features characteristic of growing axons in diverse systems^{9,18}. Of 84 axon segments examined, 42 grew at both ends, 33 grew only at the distal end, one grew only at the proximal end and 8 did not grow detectably. The distal end usually sprouted more profusely than the proximal end. Although individual branches occasionally grew 100 µm per day for up to 2 days, their average growth rate over a 6-day period was 35 µm per day or less, a rate comparable to that seen for isolated leech neurones in culture19. There was no obvious difference in the amount of growth after cuts or crushes, although following cuts those neurites that extended forwards appeared to grow across the cut surface of the nerve cord.

The two cuts or crushes separated axons into three pieces: an axon still attached to the cell body, the axon segment and the piece distal to the axon segment (Fig. 1). All the cut ends sprouted and grew at comparable rates.

To determine whether axon segments can also grow in vivo, P-cells were injected in situ²⁰ with fluorescent D-peptide. One or two days later, axons were severed by crushing the nerve cord (Fig. 1) and after a further 6 days, chains of ganglia were

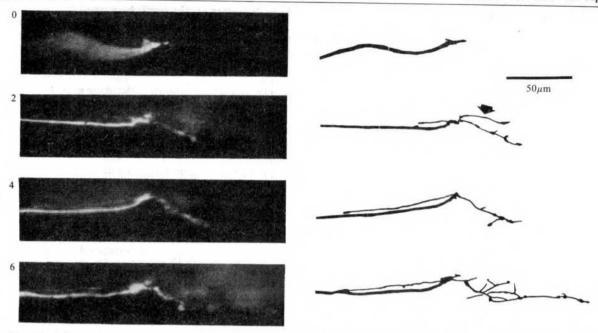

Fig. 2 Growth of the proximal end of an axon segment. Panels on the left are photographs of the video monitor screen at 2-day intervals (number of days indicated at the left) beginning 30 min after the axon was severed by crushing the nerve cord. The shallow depth of field of the objective lens reduced the amount of arborization visible in any single photograph of the monitor screen. Therefore, for each time point, tracings were made from the screen while focussing through the preparation (right-hand panels). The arrowhead indicates a neurite that apparently retracted between days 2 and 4. The preparation was viewed by epifluorescent illumination through a ×40 water immersion objective and suitable filters (Zeiss), in combination with a silicon intensified target (SIT) camera (RCA TC 1040/H), video monitor (RCA TC 1209) and video recorder (Panasonic, NV 8030). To determine the diameter of branches that were detectable with the video system, 2% HRP (Sigma, Type VI) in 0.2 M KCl with 0.2% Fast Green FCF was injected before the fluorescent D-peptide. The tissue was fixed, reacted with diaminobenzidine, and prepared for electron microscopy²². Electron microscopic examination of HRP-filled branches that had been viewed by fluorescence in the live preparation showed that branches of diameter 0.3 μm or less could be seen with the SIT camera.

removed, fixed and examined by fluorescence microscopy. Of 11 segments examined, 5 grew at both ends, 3 grew only at the distal end, one grew only at the proximal end and 2 did not grow detectably. Because the axon segments contained D-peptide, an effect of the peptide injection on growth must be considered. The fluorescent D-peptides we have used do not affect development when injected into single embryonic cells15, but we found that axons attached to P-cell bodies injected with Dpeptide sprouted less than uninjected controls (our unpublished results). This suggests that the growth of axon segments observed here may underestimate the normal growth. Axon segments of P-cells injected with horseradish peroxidase (HRP) sprouted less frequently and profusely than those injected with Dpeptide, suggesting that injected HRP inhibits nerve growth. In this context it is interesting that HRP damages frog motor nerve terminals21

The varicosities along neurites of axon segments resemble sites of sensory cell synapses in the leech^{22,23}. Synapses are formed by colchicine-treated segments of frog motor axons during their brief period of sprouting¹⁴, and leech axon segments, which survive for longer periods, may also form synapses.

The present study of leech sensory cells shows that isolated axon segments can initiate growth at both ends and grow for at least 6 days. These results support the idea that growth can be controlled locally within the cell^{24,25}. They also demonstrate that although the axonal cytoskeleton is organized in a polar fashion²⁶ and some²⁷ but not all²⁸ axonal transport is directional, axonal growth need not be intrinsically polar. Because the distal stump can be important in accurate regeneration, the possibility must be considered that sprouting by the proximal end of the stump facilitates contact and recognition between the regenerating axon and its severed stump. The source of materials necessary for growth by axon segments is unknown; they could originate either from within the axon or be transported to it from surrounding glial cells²⁹. Although the mechanism by which axons sprout and elongate is little understood, the present experiments add to the growing body of evidence indicating that

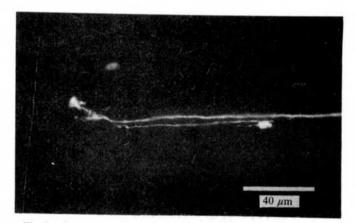

Fig. 3 A montage of fluorescence micrographs of the distal end of an axon segment filled with fluorescein—D-peptide and fixed 4 days after the axon was severed by cutting the nerve cord. The preparation was fixed in 4% paraformaldehyde in 0.1 M phosphate buffer, pH 7.4 and mounted in glycerol at pH 9.5. Several branches extended forwards and a single neurite, tipped with a large swelling resembling a growth cone, grew backwards along the axon segment.

the axon can have significant functional independence from the cell body.

We thank David Weisblat for supplying the D-peptides used in this study, Barbara Thomas for technical assistance, and Ellen Elliott and Sam Ward for useful comments on the manuscript. The voltage dependence of channel-mediated ion conduction in excitable membranes is thought to be due to rearrangement of charged groups or dipoles within the membrane in response to changes in transmembrane potential¹. This charge movement, or gating current (I_s) , has been detected in squid giant axons for Na+ channel activation^{2,3}, but no I_s has been detected which has kinetics similar to those of K^+ channel activation. This is probably due to the relatively slow time course of K+ channel activation at the temperatures normally used (6-8 °C). We report here that when the temperature is raised to 20-22 °C to increase the rate of channel activation, a new component of I_{s} is detected which shows kinetics and voltage dependence similar to those of K+ channel activation at the same temperature. In addition, the net charge moved is consistent with estimates of K channel density. We suggest that this component of I_2 is due to the charge movement associated with the rate-limiting step of K⁺ channel activation.

Experiments were performed on internally perfused squid giant axons at 20-22 °C using standard voltage-clamp techniques⁴. The internal solution contained either a mixture of potassium fluoride and potassium glutamate (for K⁺ currents) or N-methylglucamine(NMG) fluoride and NMG-glutamate (for gating currents). The external solution consisted of Na⁺-free Tris-seawater with tetrodotoxin (TTX) added. The holding potential, -60 mV, was chosen to inactivate partially the Na channel gating current5.

Figure 1 shows K⁺ ionic and gating currents recorded at 21 °C from the same axon after a voltage step to three different potentials. In all three cases the gating current contains two clearly defined components: the fast component, which is the gating current associated with Na+ channel activation, and the slow component, which is undetectable at 6 °C, and is too slow to be associated with Na+ channel activation but has a time course similar to the K⁺ currents. Figure 2a shows the voltage dependence of the time constants for K⁺ channel activation (τ_K) and the slow phase of $I_{\rm g}(\tau_{\rm g})$ for potentials from $-30~{\rm mV}$ to $+30~{\rm mV}$. The two sets of time constants correlate fairly well, indicating that this slow component may be related to K+ channel activation. Dibucaine was included in the external solution in the gating current measurements to block some of the Na+ channel gating current. At the concentration used in this study (0.2 mM), dibucaine blocks $\sim 50\%$ of the Na⁺ channel I_g without significantly affecting either the K+ currents or the slow component.

To estimate the amount of charge (Qs) responsible for the slow $I_{\rm e}$, the gating current traces were integrated from the break point in the relaxation to the steady-state level for both ON and OFF gating currents. Although this procedure minimizes any contribution from the fast component, it also ignores any slow charge movement that may have occurred from the start of the voltage step to the start of the integration period. However, as nothing is known about the shape of the early part of the slow I_z , we consider this an adequate method of estimation. We can assign an upper limit to the amount of charge movement that would not be accounted for by the above method by assuming that the slow phase extrapolates exponentially to the beginning of the pulse. When the amount of charge moved is determined in this way, we find that only 10-20% of the charge moved is missed by the original method. Figure 2b shows the voltage dependence of $Q_{s,ON}$ measured by this method: the charge moved is zero at voltages more negative than -80 mV, rises sharply as the voltage becomes more positive and finally saturates at voltages greater than zero. The saturation value of $Q_{s,ON}$ was 508 electronic charges per μm^2 ; the value for all experiments was 500 ± 90 electronic charges per μm^2 ($\pm s.d.$ of 13 determinations). $Q_{s,OFF}$ shows a similar voltage dependence and saturation value. The ratio, $Q_{s,ON}/Q_{s,OFF}$, was found to be 1.1 ± 0.2 (±s.d. of 10 determinations), as expected for a true capacitative current.

Figure 2b also shows the voltage dependence of g_K , the K^+ chord conductance (corrected for the non-linearity of the instantaneous current-voltage relation), which is a measure of the fraction of K+ channels that are in the open state. The voltage dependence of g_K is similar to that of the charge move-

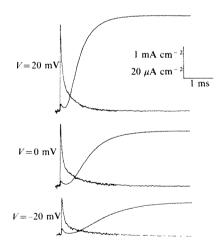

Fig. 1 Potassium $(I_K, \text{ smooth traces})$ and gating $(I_g \text{ noisy traces})$ currents recorded at 21 °C in the same axon in response to depolarizations from -60 mV to three different voltages. Leakage and capacitative currents were subtracted using the P/4 technique with the subtracting holding potential at -110 mV for both currents. I_{K} records are single sweeps and show gating current at early times. I_a traces are the average of 20 records. The external solution contained 440 mM Tris-HCl, 50 mM CaCl₂, 0.3 µM TTX pH 7.2. For gating current measurements, dibucaine (0.2 mM) was added to the external solution. Internal solutions were either 66 mM KF, 133 mM K-glutamate, 440 mM sucrose, 10 mM Tris-HCl pH 7.2 (for I_K) or 133 mM NMG-glutamate, 66 mM NMG fluoride, 440 mM sucrose, 10 mM Tris-HCl pH 7.2 (for Ig). Axon JUL211B.

ment, except that the conductance curve is shifted to the right along the voltage axis. Similar behaviour has been observed for the Na+ channel and is considered evidence for the existence of multiple closed states in voltage-dependent equilibria6.

The agreement between the kinetics and voltage dependence of the slow I_g and K^+ channel activation may, however, be fortuitous. K^+ channel activation and Na^+ channel inactivation have similar kinetics and voltage dependence, thus a linkage between Na⁺ channel inactivation and the slow I_* will also seem to hold for K⁺ channel activation. To test this possibility, we examined the effect of an 8-ms prepulse to -110 mV on the K+, Na⁺ and gating currents in response to a voltage step to 0 mV. The K⁺ currents showed a well-defined Cole-Moore shift⁷ with the activation of channels being delayed markedly (~200 µs) when the prepulse was applied (Fig. 3a). The same delay was seen for the slow I_g (Fig. 3b). Na⁺ channel inactivation, on the other hand, showed no detectable Cole–Moore shift (Fig. 3c); if it had, then the Na+ current peak after the prepulse would have shown a definite broadening, but this was not the case.

The results presented here strongly suggest that the slow I_{g} is caused by the charge movement associated with the ratelimiting step of K+ channel activation. The time course of both K^+ channel activation and the slow I_a are similar at all voltages examined. In addition, the amount of charge responsible for the slow I_g is consistent with the amount of charge moved as a K⁴ channel opens. Using the saturation value of the Q_s-V relationship (~500 charges per µm²) and estimates of the K⁺ channel density in squid giant axons (70 per μ m²; refs 8, 9), we

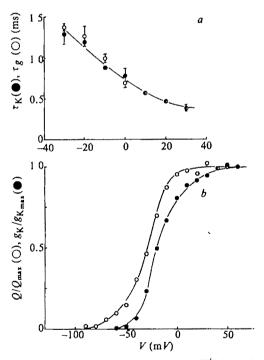

Fig. 2 Correlation of charge movement with K+ channel activation. Conditions were as described in Fig. 1 legend. a, Time constants of K^+ activation, τ_K (\bullet), were determined by fitting the current relaxation after the initial delay to a single exponential. The time constants of the slow $I_{\mathbf{g}}$, $\tau_{\mathbf{g}}$ (O), were determined by fitting the decay of the slow I_g to a single exponential. Each value is the mean ±s.d. of single determinations from three different axons: JUL211B, JUL221A and JUL221B. b, The charge moved during the slow component of ON gating current was determined as described in the text and normalized to the maximum value (508 electronic charges per μm^2 in this case) and plotted as a function of voltage (O). Also shown is the voltage dependence of the K+ chord conductance corrected for the non-linearity of the instantaneous current-voltage relation and normalized to its maximum value (●). The holding potential was -60 mV and the subtracting holding potential, -120 mV. In all cases the test pulse was preceded by an 8-ms prepulse to -110 mV to make the break point more obvious (see Fig. 3). Axons AUG181A and AUG221A.

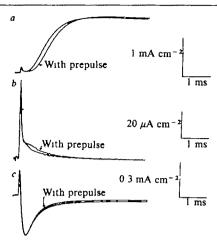

Fig. 3 Effect of a hyperpolarizing prepulse on $K^+(a)$, gating (b), and Na⁺(c) currents in response to a voltage step to 0 mV. K gating currents were measured as described in Fig. 1 legend. Trace c, which shows Na+ currents preceded by gating current, was obtained in an external solution containing 90 mM NaCl, 350 mM Tris-HCl, 50 mM CaCl₂ pH 7.2; the internal solution was the NMG solution used for gating current measurements. Where indicated, the depolarizing step was preceded by an 8-ms prepulse to $-110 \,\mathrm{mV}$. The current trace in c, obtained without a prepulse, was multiplied by 1.15 to correct for the difference in peak Na+ and gating currents. This scaling was done to account for the removal of some resting inactivation by the prepulse. Temperature, 21 °C. Axons JUL221B (I_K and I_g) and AUG261A (I_{Na}).

obtain a value of ~7 charges per channel. This agrees well with the 5-6 charges per channel expected from macroscopic conductance measurements 10,11 It is possible, however, that not all the slow charge movement detected is due to K+ channel gating currents. There may be contributions from other sources (probably Na+ channel inactivation), thus the values of Q. reported here are upper limits. Finally, the slow I_s shows a Cole-Moore shift identical to that seen for K^+ channel activation. This property represents the strongest argument we have that this slow $I_{\rm g}$ is not a charge movement associated with Na⁺ channel inactivation, but actually is the K+ channel gating current.

Gilly and Armstrong¹² recorded a slow component of I_g at 8°C that correlated with the existence of functional K+ channels. This charge movement was faster than the development of K⁺ currents, which led the authors to suggest that it represented the charge movement associated with a fast step in the activation process. The component described here, however, is not removed by destruction of K+ channels due to removal of K+ ions and, furthermore, has kinetics identical to K+ channel activation. We suggest that the slow I_s described here represents the charge movement associated with the rate-limiting step of K+ channel activation, while that described by Gilly and Armstrong is associated with a later (the last?) step in the activation process. Such a scheme has been proposed¹³ to explain the bursting patterns seen in single-channel recordings of K+ channels. Studies of the kinetic behaviour of both these charge movements in response to different pulse protocols should prove valuable in the construction and testing of models for K⁺ channel activation, as gating currents can provide information about transitions between closed states that cannot be obtained from conductance measurements

Neuropeptide Y—a novel brain peptide with structural similarities to peptide YY and pancreatic polypeptide

Kazuhiko Tatemoto, Mats Carlquist & Viktor Mutt

Department of Biochemistry II, Nobel Medical Institute, Karolinska Institute, S-104 01 Stockholm, Sweden

The C-terminal α -amide structure is a characteristic feature of many biologically active peptides^{1,2}. Using a novel chemical method for the detection of peptide amides3, we have isolated two naturally occurring peptides, peptide HI (PHI) and peptide YY (PYY), from extracts of porcine intestine and have shown that these peptide amides represent previously unknown biologically active peptides4. PHI is structurally and biologically similar to vasoactive intestinal peptide (VIP) while PYY shows similarities to pancreatic polypeptide (PP)6. Preliminary studies indicated that PHI and PYY may both be present in brain as well as in intestine4. We report here the isolation from brain extracts of a peptide amide that was thought to be PYY. However, we found that the peptide, while having distinct structural and biological similarities to both PYY and PP, is a previously uncharacterized peptide, which we designate neuropeptide Y (NPY).

NPY-containing fractions were detected from the amounts of tyrosine amide released after treatment of the lyophilized fractions with trypsin or thermolysin using a method described elsewhere^{3,5}. The brain extract and its methanol-soluble peptide fraction were prepared using procedures similar to those described previously⁷; details are given in Fig. 1 legend. The methanol-soluble peptide fraction (1.8 g), obtained from 400 kg of porcine brain, which was also used for the isolation of VIP8, was first subjected to gel filtration on a Sephadex G-25 column. The NPY fractions, which also contain secretin and VIP, were pooled and lyophilized and the lyophilized material (690 mg) was chromatographed on CM-cellulose (Fig. 1). The peptide was eluted with 0.02 M ammonium bicarbonate containing 0.025% mercaptoethanol; this procedure yielded a total of 76 mg of NPY fractions which were free from secretin and VIP. These fractions were further purified by HPLC on a reverse-phase silica gel column, μ Bondapak C-18 (Waters); see Fig. 2. The peptide was eluted with 40% ethanol/5 mM ammonium acetate/0.2% acetic acid in isocratic conditions. This step yielded a total of 16 mg of highly purified NPY fractions. A pure peptide preparation was obtained from these fractions by re-chromatography on a HPLC column using a linear gradient elution system consisting of 0.12% trifluoroacetic acid/water and 0.1% trifluoroacetic acid/acetonitrile (Fig. 3)

The peptide preparation was found to be homogeneous by amino acid analysis, N- and C-terminal determinations, and by HPLC and TLC analyses. HPLC showed that the elution profiles of this peptide were different from those of either PYY or PP. Amino acid analysis revealed that the peptide consists of 36 amino acid residues (Table 1). This peptide has tyrosine as its N-terminal residue, tyrosine amide as its C-terminal and five tyrosine (Y) residues per molecule. It was therefore designated neuropeptide Y (NPY).

The intestinal peptide PYY, like neuropeptide Y, is 36 residues long and contains an N-terminal tyrosine and a C-terminal tyrosine amide^{4,6}. PP is also 36 amino acid residues

Table 1 Amino acid compositions and N- and C-termini of the porcine peptides NPY, PYY and PP

Amino acid	NPY	o. of residues PYY	PP
Ala	4.1 (4)	4	5
Arg	4.0 (4)	4	4
Asx	5.0(5)	2	3
Glx	3.0 (3)	5	5
Gly	1.1 (1)	1	1
His	1.0 (1)	1	0
Ile	2.0(2)	0	1
Leu	3.0 (3)	4	3
Lys	1.0(1)	1	0
Met	0.0 (0)	0	2
Pro	3.9 (4)	4	2 5
Ser	2.0(2)	3	0

Tyr	5.0 (5)	5	4
Val	0.0 (0)	1	1
Total no. of residues	36	36	36
N-terminus	Туг	Tyr	Ala
C-terminus	Tyr-NH ₂	Tyr-NH ₂	Tyr-NH ₂

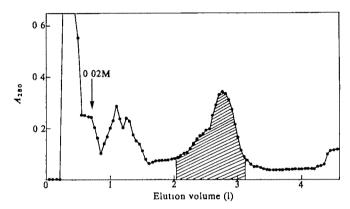

Fig. 1 Ion-exchange chromatography of NPY fraction on CMcellulose. Porcine brains (400 kg) without cerebellum and pituitary were boiled in water for 10 min, frozen and then extracted with 0.5 M acetic acid (1,000 l) for 24 h. Following filtration, peptides in the filtrate were adsorbed on alginic acid pH 2.7, eluted with 0.2 M HCl and precipitated with NaCl at saturation. The wet weight of peptide precipitate collected was ~800 g. This crude peptide material was dissolved in 161 of water then 2 vol of ethanol were added, and the pH adjusted to 7.2. After filtration, 3 vol of water were added to the filtrate, peptides in the solution were adsorbed on to alginic acid, eluted, precipitated and collected as described above. This peptide precipitate (80 g wet weight) was dissolved in water and then re-precipitated with NaCl, pH 4.0. The peptide material was suspended in methanol (41) containing 0.1% mercaptoethanol and extracted at room temperature for 15 min. After filtration, the methanol extract was neutralized by adding methanolic NaOH solution. The precipitate formed after neutralization was removed by filtration and the pH of the methanol solution readjusted to 2.7 (glass electrode) by addition of methanolic HCl. Peptides in the methanol solution were precipitated by addition of 3 vol of ether. The precipitate was collected by suction filtration and dried under reduced pressure—this yielded 1.8 g of the methanol-soluble peptide fraction. This fraction was subjected to gel filtration on a Sephadex G-25 column in 0.2 M acetic acid and the NPY-containing fractions were pooled and lyophilized. The lyophilized fraction (690 mg) was applied to a CM-cellulose column (5×20 cm) equilibrated with 0.01 M ammonium bicarbonate containing 0.025% mercaptoethanol and initially eluted with the same buffer. NPY was recovered after subsequent elution with 0.02 M ammonium bicarbonate containing 0.025% mercaptoethanol. After lyophilization, an aliquot of each fraction was subjected to the chemical assay. The NPY fractions that emerge at 2,050-3,100 ml (indicated by shading) weighed a total of 76 mg after lyophilization.

long and known to have a C-terminal tyrosine amide9. However, the amino acid composition of NPY differs from those of PYY and PP (Table 1), but it does have structural similarities to PYY and PP. PYY and NPY, in addition to identical N- and Cterminal amino acids, have equal numbers of Ala, Arg, Gly, His, Lys, Pro, Thr and Tyr residues. Further evidence of sequence similarities was provided by analysis of the tryptic fragments. Treatment of PYY with trypsin yielded five fragments⁶; trypsin treatment of NPY also yielded five fragments. two of which seemed identical to the corresponding fragments of PYY. Moreover, the N-terminal amino acids of all five tryptic fragments of NPY determined by the dansyl chloride method¹⁰ were identical to those of the corresponding fragments of PYY. Furthermore, preliminary amino acid sequence studies of the NPY tryptic fragments using the dansyl-Edman procedure¹¹ strongly suggest that NPY has further sequence similarities to PYY and PP. We have previously reported that PYY and PP are structurally related and together form a new peptide family⁶: NPY may be the third member of this novel peptide family.

PYY and NPY seem to have similarities in biological activities as well as in structure. NPY inhibited secretin-stimulated pan-

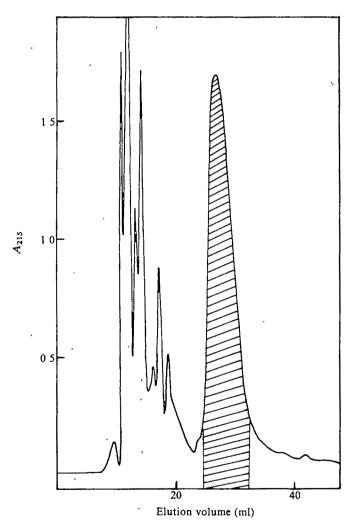

Fig. 2 A typical HPLC elution profile of the NPY fractions (see Fig. 1). The NPY fractions (2 mg per run) were applied to a reverse-phase HPLC column (µ. Bondapak C-18, 7.8×300 mm) and eluted with 40% ethanol/5 mM ammonium acetate/0.2% acetic acid at a flow rate of 2 ml min⁻¹ in isocratic conditions. The HPLC instrument (Waters) consisted of an injector (U6K), two pumps (M-6000 A), a UV detector (450 variable) and a solvent programmer (Model 660). The peak fractions were collected and concentrated to one-fifth of the original volumes under reduced pressure. After the original volumes were restored by adding water, the fractions were lyophilized and an aliquot of each was subjected to the chemical assay The NPY peak is shaded.

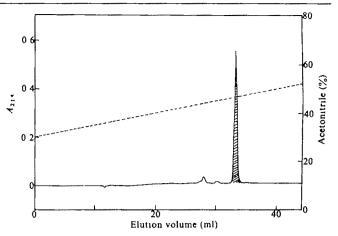

Fig. 3 HPLC elution profile of the NPY peak (see Fig. 2). The NPY fraction (25 µg) was re-chromatographed on a HPLC column (μ Bondapak C-18, 7.8×300 mm) using a linear gradient elution system (solvent A, 0.12% trifluoroacetic acid/water; solvent B, 0.1% trifluoroacetic acid/acetonitrile) at a flow rate of 2 ml min⁻¹ The NPY fraction (shaded area) was lyophilized as described in Fig. 2 legend, and then subjected to amino acid analysis and Nand C-terminal determinations.

creatic secretion in the anaesthetized cat (to be published) but was less potent than PYY⁶. PP is also known to inhibit pancreatic secretion in the dog^{12,13} but has no such effect in the cat.

Recently, many gut peptides originally isolated from the gastrointestinal tract have also been found in the central nervous system^{14,15}. However, despite increasing immunochemical evidence for the existence of many such gut-brain peptides, only a few have been isolated from both tissues and characterized with respect to their amino acid sequences. So far, these studies have indicated that the gut-brain peptides from the two tissues have identical amino acid sequences. That of NPY, however, is clearly different from its intestinal counterpart, PYY, although both peptides possess identical N- and Cterminal amino acids and have the same number of amino acid residues. An immunohistochemical study has indicated that PYY may be absent from the brain 16. We have also been unable to detect PYY in the brain, nor has the brain peptide NPY been detected in the intestine by chemical assay and HPLC techniques. It is therefore possible that NPY is found only in nerve cells and PYY only in endocrine cells.

NPY seems to be present in large quantities in the brain, at concentrations even higher than those of VIP17. Clearly, it will be of interest to determine whether NPY is a neurotransmitter or neurohormone and to discover its physiological role(s) in the central nervous system.

Acetylcholinesterase forms in fast and slow rabbit muscle

Francis Bacou & Pierre Vigneron

Institut National de la Recherche Agronomique, Station de Physiologie Animale, Place Viala, Montpellier 34000, France

Jean Massoulié

Neurobiologie, Ecole Normale Supérieure, 46 rue d'Ulm, Paris 75005, France

In the skeletal muscles of vertebrates, the level of acetylcholinesterase (AChE, EC 3.1.1.7.) may be either decreased (in rat) or increased (in chicken1 and rabbit2.3) after denervation. This enzyme is very polymorphic, however, presenting molecular forms which differ in their cellular localization and physiological regulation. The different AChE molecules may be classified as globular forms (monomers G1, dimers G2 and tetramers G₄) and asymmetric or collagen-tailed forms (containing one, two or three tetramers: A4, A8 and A12)4. The distribution of the collagen-tailed and globular forms along the muscle fibres varies according to the animal species and physiological state: in normal adult rat muscle, the A12 form, which represents the major collagen-tailed form, is localized exclusively in the endplate region⁴⁻⁶, whereas in rat embryo⁷ and human muscle8 this form is distributed over the entire muscle fibre. The presence of collagen-tailed AChE has, however, been considered as an indicator of neuromuscular interactions because its appearance during embryogenesis coincides with the establishment of neuromuscular contacts^{6,9} and because, after denervation, the A12 form disappears from rat5,6 chicken10,11 muscles. Here we report that this form in fact increases markedly in a slow twitch oxidative muscle of the rabbit after denervation. The regulation of asymmetric-and particularly A12-forms of AChE thus depends dramatically on the species and on the nature of skeletal muscle.

One of the large muscles of the rabbit leg, the semimembranosus, consists of two very distinct and remarkably homogeneous parts12,13: the external region (region I) contains fast twitch type II glycolytic fibres and the internal conoidal bundle (region II) contains only slow twitch type I oxidative fibres (Fig. 1a) (P.V. and F.B., in preparation). Figure 2 illustrates an analysis of the AChE content of endplate-containing and endplate-free segments of these two muscle regions. In region I, the aneural sections contain very little AChE activity, while in region II, the specific activity is about half that of the endplatecontaining segments. In both fast and slow muscle regions, however, the collagen-tailed forms are preferentially, or exclusively, localized in the endplate-containing segments (the small proportion which is observed in the aneural samples may be due to the presence of a few endplates which have not been detected). In addition, the globular forms are also concentrated in the neural segments.

The semimembranosus muscle was usually denervated by removing a segment of the corresponding sciatic branch (the rest of the leg remaining mobile). After denervation, we noted a marked atrophy particularly affecting region I of the muscle (Table 1) and, by 2 months, an extensive infiltration of fatty inclusions. Although the red colour of the conoidal region II became paler, the two parts of the muscle remained very distinct. Figure 1b shows the histochemical appearance of the muscle after prolonged denervation. The slow type I fibres of region II are markedly atrophied and keep their acid-stable ATPase properties, whereas the fast type II fibres of region I are more heterogeneous, both in size and ATPase activities.

Table 1 shows that after denervation, AChE activity and acetylcholine receptors (AChR) rose to very high levels, reaching similar values in the two muscle regions at 2 weeks. The receptor level then continued to increase in region I, which became

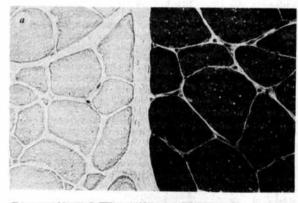

extensively atrophied. Although the receptor level appeared to decrease in region II, it remained at the high level characteristic of denervated muscle, and it seems unlikely that this interior muscle bundle could be re-innervated while the external mass of the muscle was not. Indeed, we never observed any sign of re-innervation in our experiments.

In denervated muscles, the AChE activity increased markedly, reaching about 10 times the original level in both muscle regions 1 month after the operation. It then continued to increase in region I, but decreased slightly in region II. After very long denervation periods (6 months), the slow conoidal bundle (region II) retained its characteristics, but the fast external part (region I) presented a very profound fatty degeneration, and no longer contained significant AChE activity.

Figure 3 illustrates the changes occurring in the composition of AChE molecular forms in regions I and II after denervation. The proportions of the various molecular forms were estimated from the sedimentation patterns, and used to determine their specific activities (see Table 2). In region I, the smaller globular forms increase after denervation, while the collagen-tailed forms decrease gradually, essentially disappearing 1 month after the operation. They reappear later in significant proportion (Fig. 3).

Region II follows a very different evolution: there is a marked increase of the collagen-tailed forms, both in proportion and in absolute level, which is maintained for at least 2 months.

We obtained very similar results when the sciatic nerve was transected near its root, paralysing the whole leg. Thus, a passive mechanical activity of the denervated muscles does not modify their evolution markedly.

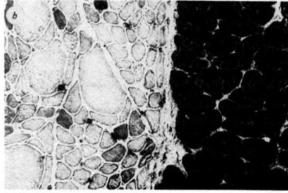

Fig. 1 Histochemical characterization of normal and denervated fast and slow regions of the rabbit semimembranosus muscle. Transverse sections of normal (a) or denervated (3 months) (b) semimembranosus muscle showing the limit between the external rapid part (region I, left) and the internal slow conoidal bundle (region II, right) stained for myofibrillar ATPase at pH 4.15 (×160). The light-coloured fibres of region I are fast-twitch type II, and the darkly stained fibres of the conoidal region II are slow-twitch type I. Cross-sections 14 μm thick were cut at $-15\,^{\circ}\mathrm{C}$ and stained for myofibrillar ATPase according to the method of Padykula and Herman 26 , modified by Guth and Samaha 27 . The staining procedure involved 12 min preincubation at 4 $^{\circ}\mathrm{C}$ in 1 M formic acid–NaOH buffer (pH 4.15), followed by 60 min incubation (37 $^{\circ}\mathrm{C}$) in 0.1 M barbital buffer, containing 18 mM CaCl $_2$ and 5 mM ATP (pH 9.4).

The present experiments show that the fast and slow parts of the rabbit semimembranosus muscle maintain their individuality for a very long time after denervation. Muscle types are thus very stable in the absence of innervation. We have in fact shown previously that distinctive characteristics may develop in nerve-free cultures of chick myoblasts obtained from muscles which in the adult become slow or fast¹⁴.

The difference in the evolution of the fast (region I) and slow (region II) parts of the denervated semimembranosus muscle is

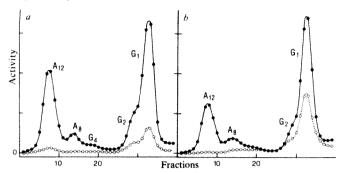

Fig. 2 Sedimentation profiles of AChE in endplate-containing and endplate-free sections of the fast (region I) and slow (region II) parts of the rabbit semimembranosus muscle, a. Region I; b. region II. . Endplate-containing segments; O, aneural segments. Small groups of fibres were teased from the two regions of the muscle, and endplates were visualized by the method of Koelle and Friedenwald, modified by Koenig and Rieger²⁸, which does not inactivate AChE. Neural and aneural segments could thus be dissected. They were homogenized in a glass-Teflon Potter homogenizer, with 10 vols of extraction medium containing antiproteolytic agents (NaCl 1 M, Triton X-100 1%, Tris-HCl pH 7, 10 mM, benzamidine 1 mM, bacitracin 1 mg ml⁻¹, Zymofren (aprotinin) 25 U ml⁻¹). Aliquots of the extracts were layered on 5-20% w/v sucrose gradients in saline detergent buffer (NaCl 1 M, MgCl₂ 50 mM, Triton X-100 1%, Tris-HCl pH 7 10 mM, bacitracin 0.1 mg ml⁻¹), and centrifuged in a Beckman SW 41 rotor, at 40,000 r.p.m. and 4 °C, for 20 h. *Escherichia coli* β -galactosidase (16S), beef liver catalase (11.3S) and calf intestine alkaline phosphatase (6.1S) were included as internal sedimentation standards, as described previously4. The apparent sedimentation coefficients of the AChE forms were approximately 16.2S (A_{12}) , 13S (A_8) and 8.5S (A_4) for the asymmetric forms, and 10.5S (G_4) , 5S (G_2) and 3S (G_1) for the globular forms. The asymmetric, collagentailed forms were characterized by their aggregation properties; they were no longer visible if the gradient was prepared without NaCl. The specific activity of AChE in aneural segments of region I was very low (0.8 nmol per min per mg protein), compared with that of endplate-containing segment (5.7 nmol per min per mg protein). In the case of region II, the specific activities of aneural and neural segments were, respectively, 3 and 7.6 nmol per min per mg protein. AChE activity is plotted on an arbitrary scale but the profiles corresponding to the neural and aneural samples of each region have been normalized so that the activities of each form in the two segments are directly comparable.

particularly remarkable with respect to the collagen-tailed forms of AChE. In region I, the localization and evolution of AChE appear somewhat similar to those previously observed in chicken fast-twitch muscle: the activity is highly concentrated at the endplates in the normal muscle¹⁵, and after denervation there is a concomitant decrease of the A₁₂ form and increase of the small globular forms. In contrast, the dramatic increase in the A₁₂ collagen-tailed form which occurs in the denervated region II of semimembranosus disagrees with previous observations in other species, which suggested that this form disappeared from all skeletal muscles after denervation, even when the overall level of AChE was elevated. This increase shows that the continued presence of the nerve is not necessary for the biosynthesis of collagen-tailed AChE forms, a conclusion reinforced by the reappearance of the A₁₂ form in the fast region (I) of the muscle after prolonged denervation.

In addition, the very high level of A_{12} , and to a lesser extent A_8 , in denervated region II indicates that these forms are probably not limited to the original sites of neuromuscular contacts. Indeed, we found that segments from 1-month denervated region II, corresponding to originally endplate-containing and endplate-free regions, contained exactly the same AChE activity with the same pattern of molecular forms, in particular a high proportion of A_{12} form.

The histochemical analysis of Tennyson et al.³ showed that after denervation, the AChE activity increases mostly in the extrajunctional part of the muscle fibres, notably at intracellular sites, and is largely associated with the sarcoplasmic reticulum. It is thus very likely that a fraction of the molecular forms synthesized in such conditions, including the collagen-tailed forms, remain intracellular, associated with the reticulum. One example of such an intracellular localization of collagen-tailed forms has been reported in the case of motor nerves, where these molecules are transported by fast axonal flow¹⁶.

The present observations do not contradict the hypothesis that neuromuscular interactions are required to trigger the biosynthesis of the collagen-tailed forms: Koenig and Vigny¹⁷ found that muscle cells from 13-day-old rat embryos only synthesize the A₁₂ form when cultured in the presence of neurones, but that myoblasts obtained from 18-day-old embryos possess the capacity to synthesize this form by themselves. Rubin et al. ¹⁸ have also demonstrated an induction of the A₁₂ form in cultures of chick myotubes, by synaptic contacts with cholinergic neurones, while Kato et al. ¹⁹ found that this enzyme is synthesized in cultures of muscle cells isolated from innervated muscles of 11-day-old chick embryos. These findings

Table 1 Evolution of AChE and acetylcholine receptors in fast (I) and slow (II) regions of rabbit semimembranosus after denervation

		Control muscle	2 Weeks denervated muscle	1 Month denervated muscle	2 Months denervated muscle
Fast twitch	Total weight of muscle (g) AChE (nmol per min per mg protein) AChR (pmol per mg protein)	20.8	11.1	6.0	5.8
semimembranosus		2.2	13	29.3	62.1
region (I)		0.01-0.02	0.34	0.47	0.76
Slow twitch	Total weight of muscle (g) AChE (nmol per min per mg protein) AChR (pmol per mg protein)	2.23	1.76	1.10	1.42
semimembranosus		4.3	15.7	41.6	30
region (II)		0.01–0.02	0.34	0.19	0.15

The rabbits used were New Zealand white females weighing 2.800-3.100 kg. The weight of the muscle has been normalized for 3 kg body weight. The specific activity of AChE was determined in muscle extracts obtained in a detergent saline buffer containing antiproteolytic agents (Tris-HCl, pH 7 10 mM, EDTA 10 mM, NaCl 1 M, Triton X-100 1%, benzamidine 1 mM, Zymofren (aprotinin) 25 U ml⁻¹, bacitracin 1 mg ml⁻¹. AChE activity was determined by the spectrophotometric method of Ellman and colleagues²⁴ as described previously⁴ in the presence of 10⁻⁵ M ethopropazine, an inhibitor of nonspecific cholinesterase. The extract was preincubated for at least 1 h in the reaction mixture in the absence of the substrate acetylthiocholine, in order to avoid interference with the reaction of sulphydryl groups in the extract with 5, 5'-dithio-bis(2-nitrobenzoic)acid (DNTB). We verified that the preincubation of AChE with DNTB did not modify its activity. The activity of the 'nonspecific' cholinesterase (EC 3.1.1.8.) was negligible in the muscle extracts, even after denervation. AChR were assayed by measuring the binding of ¹²⁵I-labelled bungarotoxin (NEN) (10-20 µCi per µg) to a membrane preparation obtained in the following manner. A sample of finely minced muscle was homogenized with a Polytron homogenizer in 10 vol of buffer (Tris-HCl, pH 7.5, 50 mM, EDTA 3 mM, EGTA 1 mM, phenylmethylsulphonylfluoride 0.1 mM, aprotinin (Sigma) 5 trypsin inhibitor units per 1). The homogenate was filtered through a nylon sieve to eliminate the fibrous material. After centrifugation at 20,000g for 30 min, the pellet was resuspended in 5 vol of buffer and aliquots of this particulate suspension were incubated for 2 h at room temperature with a saturating concentration of labelled bungarotoxin (8 nM). In control samples a 100-fold excess of cold erabutoxin was added 1 h before the labelled toxin. After incubation, the suspension was diluted with 2 ml cold buffer, centrifuged and the pellet was resuspension was collined buffer, before coun

Table 2 Evolution of AChE molecular forms in denervated rabbit semimembranosus muscle

		Control muscle	2 Weeks denervated muscle	1 Month denervated muscle	2 Months denervated muscle
Fast twitch semimembranesus region Specific activity (nmol per min per mg total protein) and proportion of total activity	A ₁₂ (16.2S)	0.8 (36%)	0.6 (4.5%)	(<0.5%)	1.2 (2%)
	A ₈ (13S)	0.2 (10%)	0.4 (2.5%)	(<0.5%)	07 (1%)
	G ₄ (10.5S)	0.1 (4%)	0.5 (5%)	3 2 (11%)	76 (12%)

	G ₁ (3S)	3.0 (69%)	10.7 (68%)	19 6 (47%)	14.1 (47%)

The proportions of the various molecular forms were estimated from the sedimentation profiles (Fig. 3), and the specific activity of each form was then obtained from the total AChE activity, given in Table 1. Although the minor asymmetric A4 form represents a significant component in some cases (for example, ~5% in the central slow region), its contribution is generally negligible and is not listed.

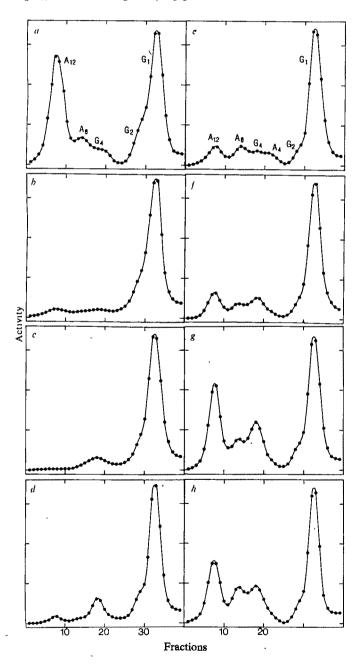

Fig. 3 Sedimentation profiles of AChE in the fast (region I) and slow (region II) parts of the normal and denervated rabbit semimembranesus muscle. a-d, region I; e-h, region II The muscle was finely minced with a scalpel; aliquots of the mince were crushed into a powder in liquid nitrogen, homogenized in a Teflon Potter homogenizer and the extracts were analysed as indicated in Fig. 2. The proportions and specific activities of the different forms of AChE are reported in Table 2

suggest that nerve-muscle interactions occurring in vivo may leave permanent instructions allowing the assembly of collagentailed AChE in culture. The presence of the A₁₂ form in cultures of a transformed murine muscle line19 indeed shows that this capacity can be transmitted indefinitely.

It seems likely that the proportion of the different molecular forms of AChE observed in normally innervated muscles in vivo corresponds to specific physiological requirements; the different forms possess distinct interaction properties4 and their proportions therefore control the spatial distribution of the enzyme within synaptic structures. For example, the ionic interactions of the collagen-tailed forms²⁰ may anchor them in the intersynaptic basal lamina²¹. These forms might be specifically required in neuromuscular junctions at which transmission is effected by impulses of very short duration: in normal adult chickens, the A₁₂ form becomes largely predominant in the phasic, focally innervated posterior latissimus dorsi muscle but disappears in the tonic anterior latissimus dorsi muscle²².

In conclusion, the nerve seems to exert a twofold influence on the muscle: an initial induction effect which allows the synthesis of collagen-tailed AChE and possibly determines the type of fibre—although this can be modified, for example, by reinnervation with a different neurone—and a functional regulation which requires its continued presence. This second effect is probably mediated in part through the muscle's activity23, perhaps by the intracellular level of cyclic GMP¹⁸. Denervated muscles apparently escape this physiological regulation, producing either increased or decreased levels of AChE, with highly variable patterns of molecular forms, depending on the species, and on the type of muscle.

We thank Marylène Rostagno and Pierre Allemand for technical assistance, and Dr. Robert Oswald for help with the acetylcholine receptor assays. A rat monoclonal antibody against mouse α and β interferon

of all molecular weight species

Monoclonal antibodies have proven to be invaluable reagents for the characterization and purification of human interferons (IFN). Hybridoma lines secreting monospecific antibodies against human IFN- α and IFN- β have been isolated, and these antibodies have shown no cross-reactivity between the two interferons¹⁻⁴. Murine interferons, when analysed by polyacrylamide gel electrophoresis, have two major migration patterns, one in the 28,000-35,000 (28-35 K) molecular weight (M_r) region and the second in the 22 K region⁵⁻⁸. Based on some homology of the N-terminal amino acid sequence with human interferons, the 28 K and 35 K species are classified as mouse IFN-B and the 22 K species as mouse IFN- α^9 . Minor species have also been described but their relationship to IFN- α and IFN- β is unknown^{10,11}. We have now established a stable hybridoma line secreting rat antibodies to mouse virus-induced interferon. The monoclonal antibodies are of the IgG class, with binding activity to all the different M, specied, as demonstrated in an enzyme-linked immunosorbent assay (ELISA) and by affinity chromatography. In addition, the antiviral activity of all the M_r species was neutralized by the antibody but the neutralizing activity was much weaker than the binding activity. This indicates the presence of a common antigenic site for all mouse α and B interferon species.

The interferon used for immunization was elicited with Newcastle disease virus (NDV) in monolayer cultures of Swiss mouse C-243 cells as described elsewhere 10. Purification was performed by two-step affinity chromatography on poly(U)-Sepharose and anti-interferon antibody-coupled Affigel-10 columns. The antibody used for this purification consisted of the globulin fraction of serum from a goat immunized with NDVinduced C-243 cell mouse interferon. The specific activity of the purified interferon was 2.4 × 10° U per mg protein (all interferon units are expressed as international reference units) and its electrophoretic purity was assessed on 15% polyacrylamide slab gels in the presence of SDS in a Tris-glycine buffer system⁸. The biological activity of interferon preparations was determined by measuring the protection from the cytopathic effect of vesicular stomatitis virus on L929 cell monolayers.

An 8-week-old female rat of the LOU strain received $5 \times$ 10⁷ U of purified interferon in complete Freund's adjuvant subcutaneously (s.c.) and intraperitoneally (i.p.). This corresponds to 50 μ g of interferon if calculated with a specific activity of 2.4×10^9 U (ref. 8). A second set of injections (s.c. and i.p.) with 2.5×10^7 U (25 μ g) of purified interferon was given 3 weeks later in incomplete Freund's adjuvant. After 3 weeks the animal received 0.5×10^7 U (5 µg) of purified interferon i.p. on 3 consecutive days. The rat produced serum antibodies against interferon, with a neutralizing titre of 1/8,000 as measured against 4 interferon units. It was killed 2 days after the last injection and spleen and mesenteric lymph nodes were aseptically removed. The cells were fused with LOU-derived 210RCY3-Agl.2.3 rat myeloma cells¹² according to the protocol of Köhler and Milstein¹³ modified by Fazekas et al.¹⁴. After fusion, the cells were cultured in Falcon Microtest plates at a density of 8×10^5 spleen cells per well on mouse peritoneal macrophage feeder layers in hypoxanthine-aminopterin-thymidine medium; 960 wells were seeded. Supernatants of growing hybridoma colonies were tested for binding activity using an ELISA. Microelisa plates (Dynatech, M 129B) coated with purified interferon were filled with 50 µl of hybridoma supernatant and kept at 37 °C for 30 min. After washing, horseradish peroxidase-conjugated rabbit anti-rat immunoglobulin preparations (Cappel Laboratories) were used as indicator antibody in 1:200 dilution in phosphate-buffered saline (PBS) containing 3% bovine serum albumin (BSA) and 1% Tween 20. After 30 min incubation at 37 °C the wells were washed and for the colour reaction, 100 µl of 25 µg o-phenylenediamine per ml of 10 mM phosphate buffer, pH containing 0.02% H₂O₂ (30%) were added. The reaction was terminated after 20-30 min with 50 µl of 3M HCl and absorption was read at 492 nm. Of the 960 wells seeded, 250 were positive for hybridoma growth, and the supernatants of 17 of these gave a positive ELISA reaction (twice the background reading), but only one (clone C5A) was found to be stable after two subclonings. Cells from wells containing supernatant active in ELISA were immediately subcloned by limiting dilution and supernatants from subclones tested. In this way a stable hybridoma line secreting monoclonal antibodies binding to electrophoretically pure interferon was established. The antibody belongs to the rat IgG class, as determined by immunoprecipitation, gel filtration and electrophoresis on 15% polyacrylamide gel in the presence of 0.1% SDS and 1% \(\beta\)-mercaptoethanol. The secretion of antibodies was checked regularly and the cell line found to be stable for

For mass production of antibodies, adult male rats (LOU) were injected i.p. with 2 ml of Pristan mineral oil and 1 week

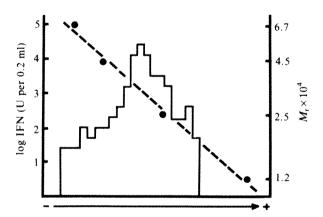

Fig. 1 Electrophoretic profile of interferon activity eluted from polyacrylamide gels after affinity chromatography on monoclonal antibodies fixed to Affigel-10 (Biorad). To prepare the column, ammonium sulphate-precipitated antibodies derived from 50 ml ascites fluid was coupled to the Affigel in 100 mM phosphate buffer, pH 7, at 4 °C. Free binding sites were saturated with ethanolamine and the column washed with a cycle of 100 mM phosphate buffer pH 7 and then with a cycle of 100 mM citrate buffer, pH 2.2. Interferon purified on poly(U)-Sepharose $(7.7 \times$ 10⁵U) was applied to the column. No interferon activity was recovered in the flowthrough. After a washing step, the bound interferon was desorbed with citrate buffer, pH 2.2. The peak fractions were pooled, dialysed against 125 mM Tris buffer, pH 6.8, containing 1% SDS then concentrated on an Amicon PM10 membrane and boiled with 1% β-mercaptoethanol for analysis on a 15% polyacrylamide gel in the presence of 0.1% SDS. Molecular weight markers consisted of BSA (67,000), ovalbumin (45,000), chymotrypsinogen (25,000) and cytochrome c (12,500). For the determination of interferon activity, 2-mm slices were cut and eluted overnight at 4 °C.

Table 1 Neutralization of the antiviral activity of the different M_r species of murine interferon

_	log :	IFN titre
$M_r(\times 10^3)$	Control	+ Antibody
65	3.28	2.68
35	5.38	4.78
28	4.48	3.88
22	3.28	2.98
15	2.38	2.07
Unfractionated IFN	5.88	5.28

Interferon purified on poly(U)-Sepharose⁸ was electrophoretically separated on 15% polyacrylamide gels in the presence of 0.1% SDS and 1% β -mercaptoethanol. 1-mm slices of the gel were eluted overnight in 0.2 ml of Tris-SDS 0.1%. The antiviral activity of the eluates was determined in the presence or absence of 2.5 µl of antibody-containing ascites fluid at each dilution of the samples and expressed as \log_{10} of the interferon titre. Comparable results were obtained when the antibody was prepared from supernatants of hybridoma cultures. The results of four different neutralization experiments indicated no significant difference in the degree of neutralization of the various M_r species. Supernatants of myeloma cultures, concentrated and treated like the hybridoma supernatants, were without effect.

later with $5-10\times10^6$ hybridoma cells, also i.p. One to two weeks later ascites fluid was recovered from the peritoneal cavity and IgG purified by ammonium sulphate precipitation, sometimes followed by gel filtration on Sephacryl-S300. The interferonbinding activity in ELISA from the ascites fluid was 1,000-fold higher than that from culture supernatants.

When crude mouse interferon, consisting of a mixture of all $M_{\rm r}$ forms, was tested in the presence of purified monoclonal antibody, the antiviral activity was significantly reduced. However, the neutralizing titre was considerably lower than the binding titre, since an antibody preparation giving a positive ELISA reaction at a dilution of 1/12,800 completely neutralized 4 U of mouse interferon only at a dilution of 1/32, or lower.

Anti-interferon antibodies from culture supernatant were retained by protein A-Sepharose in binding conditions via the Fc part of the IgG molecule. Crude interferon was applied to the column after extensive washing, antigen-antibody complexes were desorbed. The elution pattern of interferon activity desorbed at pH 3, after electrophoresis on 15% polyacrylamide gel in the presence of SDS, shows that the protein A-Sepharose coated with the monoclonal antibodies retained both IFN-α (22 K) and IFN- β (28-35 K). Insufficient interferon was used in this experiment to allow detection of the 65 K and 15 K species. Additional evidence for binding to all interferon species was then obtained by affinity chromatography on monoclonal antibodies bound to Affigel-10. In these conditions, there was complete retention of NDV-induced C-243 interferon and the bound interferon could be desorbed by lowering the pH with 0.1 M Na-citrate buffer. Because the major α and β interferon species are present in about equivalent amounts in our crude C-243 cell interferon preparation, as shown by neutralization with anti-mouse IFN- β serum, total retention by the column is indicative of affinity for all M_r forms. This was confirmed by an electrophoretic analysis of the interferon desorbed from the column which showed that the major M_r forms were present in the desorbed material (Fig. 1). The minor 15 K species was not recovered from the gel, but affinity of the antibody for this species was demonstrated in the following experiments.

To determine the capacity of the antibody to neutralize all the different mouse interferon species, a preparation of NDVinduced C-243 interferon, prepared as described previously 10, was purified and concentrated on poly(U)-Sepharose. An aliquot of the peak fraction, with a titre of 2.4×10^7 U, was dialysed overnight against sample buffer (0.125 mM Tris pH 6.8, β -mercaptoethanol 1%, SDS 0.1%) and after boiling for 2 min, electrophoresed on a 15% polyacrylamide slab gel as described previously⁸. The gel was cut into 1-mm slices which

were eluted overnight in 0.2 ml of Tris-SDS 0.1% per slice. Titration of the interferon activity of all fractions in the presence or absence of themonoclonal antibody revealed the presence of the two major peaks, one at 28-35 K (murine IFN- β) and one at 22 K (murine IFN- α) and the two minor peaks of 65 K and 15 K. The antiviral activity of all the fractions was reduced by a factor of two to four in the presence of the antiserum: the results for the peak fractions are summarized in Table 1. Affinity of the antibody for all the M_r forms was then confirmed in an ELISA assay, in which a 50-µl aliquot of each fraction was left to adsorb to Microelisa plates (Dynatech M129) overnight at room temperature. The reaction was then carried out as described above, using antibody obtained from ascites fluid. A positive reaction was scored in all the wells that had received the fractionated interferon, from 65 K to 15 K down.

All previously described monoclonal antibodies against human interferon show specificity for either IFN- α or IFN- β . Recently, a monoclonal rat antibody against mouse IFN-B has been obtained that did not bind mouse IFN- α^{15} . Therefore, it is rather surprising that the first monoclonal antibody we obtained after immunizing a rat showed no specificity in binding to a particular mouse interferon species but instead binds to all of them. Antigenic differences between mouse IFN- α and IFN- β have been described by Yamamoto and Kawade¹⁶, who immunized rabbits against the fast- and slow-moving components of NDV-induced mouse L-cell interferon. The antisera they obtained showed some cross-reactivity as measured by binding of interferon to immobilized antibody columns and the authors attributed this to possible crosscontamination of the interferons used for immunization.

The results with the monoclonal antibody presented here suggest that the antisera of Yamamoto and Kawade may well have contained cross-reacting antibodies. Tryptic digests of the high M_r species (40 K, corresponding to mouse IFN- β) and the low M_r species (24 K, corresponding to mouse IFN- α) of mouse L-cell interferon have revealed the presence of a common polypeptide structure¹⁷ and regions of homology have also been found in the amino acid sequence of human α and β interferons 18. As indicated by the results of the binding and neutralization experiments with the rat monoclonal antibody that we have obtained, at least one antigen site is shared by all M_r forms of mouse interferon. This may be a highly conserved region of some importance for the activity of the different interferon species.

We thank J. Hurst and L. Eusèbe for technical assistance, T. Ternynck for introducing us to the ELISA technique, Dr E. Günther for the gift of LOU rats, and Dr L. Kronenberg for providing us with anti-mouse IFN- β rabbit serum. D.M. was supported by a fellowship of the Deutsche Forschungsgemeinschaft and is at the Deutsches Krebsforschungszentrum, Heidelberg. R.K. is at the Friedrich Miescher Institut, Tübingen. This work was supported by the Foundation pour la Recherche Médicale Française and the Ligue National Française contre le Cancer.

Monoclonal antibodies against unique *I*-region gene products expressed only on mature functional T cells

Kelichi Hiramatsu, Atsuo Ochi, Seiji Miyatani, Akihisa Segawa & Tomio Tada

Department of Immunology, Faculty of Medicine, University of Tokyo, Bunkyo-Ku, Tokyo 113, Japan

The immune response (I) region of the murine major histocompatibility complex (MHC) regulates specific immune responses against antigens1 and encodes cell-surface molecules designated as Ia antigens². Ia antigens are generally detected on B cells and macrophages, and have important roles in immunocyte interactions. On the other hand, it has been reported that some T cells and their products (antigen-specific T-cell factors) carry unique I region-encoded determinants which are different from B-cell Ia antigens³⁻¹⁰. As T-cell factors are known to mediate T-T and T-B cell interactions11, elucidation of such unique I-region determinants on T cells is obviously important for understanding the regulatory cell interactions of the immune response. However, this has long been hampered by the lack of reagents specific for the determinants and due to the small number of T cells expressing them. To overcome this difficulty, cell hybridization techniques have been used to develop T-cell hybrids which continuously express I-region products, and monoclonal antibodies specific for these determinants have been produced. Here we report the production of monoclonal antibodies which detect a unique set of I-region determinants expressed only on functional subsets of T cells and T-cell hybridomas.

The rationale used in this study was based on our previous findings that antigen-specific augmenting (T_*F) and suppressor (T_*F) factors produced by immune splenic T cells of mice carry *I*-region determinants encoded in the *I-A* and *I-J* subregions of the MHC^{6,9}. Both these determinants are distinct from B-cell Ia antigens with respect to molecular size, composition, antigenspecific regulatory function and serological cross-reactive pattern. In addition, they possess antigen-binding sites with idiotypes and immunoglobulin variable region determinants ¹². These properties suggest that the Ia antigens associated with

T-cell factors may have prototypic structures entirely different from those of conventional B-cell Ia antigens, which consist of α and β polypeptides¹³.

We have obtained T-cell hybrids which produce antigen-specific T_*F and T_*F with I region-encoded determinants^{14,15}. Such hybrids are apparently ideal tools for screening monoclonal antibodies reactive to putatively unique T-cell Ia antigens. We therefore produced monoclonal antibodies which react specifically with these determinants expressed on T-cell hybrids. Spleen cells of A.TH (H-2¹²) mice immunized with A.TL (H-2^{t1}) lymphoid cells were fused with P3-X63-Ag-8-653, a 8-azaguanine-resistant plasmacytoma of BALB/c mouse origin. Strains A.TH and A.TL differ only in the I and S regions of the MHC, thus spleen cells of immune A.TH mice should contain B cells specific for I-region products of $H-2^k$ haplotype. The fused cells were selected in hypoxanthine-aminopterinthymidine medium, and were cloned by limiting dilution. The culture supernatants of cell lines were screened for antibody activity against a T-cell hybrid (FL10) of A/J mouse origin, which had been shown to produce T_aF specific for keyhole limpet haemocyanin (KLH) associated with a unique product of the I-A subregion of $H-2^a$ (ref. 14).

The supernatants of 31 out of 201 clones were reactive with FL10 in a microcytotoxicity assay and in fluorescence-activated cell sorting (FACS) analysis of two fusion experiments. Those clones which stained parental thymoma, BW5147, and Ianegative T-cell hybrids were excluded. They were further screened with spleen cells of nude C3H mice $(H-2^k)$, and only those which did not react with B cells and macrophages were selected. Eleven clones were finally established using the criteria that their antibodies reacted with FL10 but not with BW5147 and $H-2^k$ B cells (Table 1).

The monoclonal antibodies were tested further with enriched antigen-binding T cells of A/J $(H-2^a)$ mice prepared by adsorption of KLH-primed splenic T cells to antigen-coated plastic dishes¹⁶; A/J mice produce augmenting T cells expressing $I-A^k$ but are unable to make $I-J^+$ suppressor T cells on immunization with KLH⁹. All the antibodies reactive to FL10 were, in fact, strongly cytotoxic for the enriched KLH-binding T cells of A/J but were unable to kill non-antigen binding T cells (Table 1). They were also unable to kill normal splenic and thymic T cells of both A/J and C3H, suggesting that the proportion of T cells expressing these I-region determinants is too small to be estimated by the usual cytotoxicity test. The

Screening of monoclonal antibodies using the T-cell hybrid, FL10, and KLH-binding T cells. Culture supernatants of hybrid clones were tested for reactivity to various preparations of normal cells, as well as to the Ia-positive T-cell hybrid, FL10, by the dye exclusion cytotoxicity test. 20 μ l of culture supernatant were mixed with the same volume of cell suspension $(2 \times 10^6 \text{ ml}^{-1})$ and incubated at room temperature for 15 min. After washing, 20 μ l of selected rabbit complement were added, and the mixture was incubated at 37 °C for 30 min. Per cent lysis was calculated using the formula $(a/b)/(100-b)\times 100$ where a= percentage of cells stained by Trypan blue after incubation with the culture supernatant and complement, and b= percentage of cells stained after incubation with complement alone. KLH-binding T cells of A/J mice were prepared from spleen cells of KLH-hyperimmunized A/J mice. Spleen cells were first layered onto plastic dishes coated with purified anti-mouse immunoglobulin to remove B rigorous washing with chilled medium, and were used as KLH-binding T cells. Nonadherent T cells were used as control. Isotypes of the monoclonal antibodies were determined by double immunodiffusion with purified anti-isotype antibodies. ND, not determined.

T-cell specificity of the monoclonal antibodies was confirmed by absorption of culture supernatants with A/J splenic B cells obtained by treatment with a rabbit anti-brain antiserum and complement (C): after absorption, the cytotoxic activity for FL10 remained intact, whereas absorption with unseparated spleen cells removed the antibody activity (Table 2). This result indicates that some T but not B cells express the *I*-region determinants detected by our monoclonal antibodies.

Haplotype and *I*-subregion specificities of the monoclonal antibodies were determined by absorption with splenic T cells of different strains (Table 2). Absorption with spleen cells of A/J, A.TL, B10.BR $(H-2^k)$ and B10.A(4R) eliminated the ability to kill FL10, whereas absorption with A.TH and B10.S $(H-2^i)$ cells failed to do so. Cytotoxicity for FL10 was not removed by absorption with B10 $(H-2^b)$ spleen cells, except for one (21L27) which showed a definite cross-reactivity with the $H-2^b$ haplotype. These results indicate that the antibody specificity is directed primarily at the product of the I-A subregion of $H-2^k$. All the monoclonal antibodies were entirely refractory in their cytotoxicity for virus-producing T lymphomas such as E&G2 $(H-2^d)$, EL-4 $(H-2^b)$ and AKSL-2 $(H-2^k)$, which excludes the possibility that they are antiviral antibodies.

Having established that these monoclonal antibodies consistently react with *I-A*⁺ FL10, we performed experiments to determine whether they are actually detecting *I*-region determinants selectively expressed on certain functional T-cell

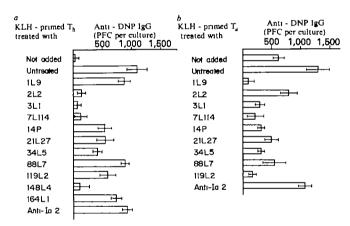

Fig. 1 a, Effect of monoclonal antibodies on the KLH-specific helper T cell (Th). DNP-primed B cells were obtained from spleen cells of DNP-KLH-primed mice after treatment with rabbit antibrain antibodies and complement. They were co-cultured with KLH-specific syngeneic helper T cells obtained by incubating KLH-primed spleen cells in plastic dishes coated with rabbit anti-mouse immunoglobulin (anti-MIg). The KLH-primed splenic T cells were treated with monoclonal antibodies (~0.1 μg antibody) and complement before the co-culture with B cells. Anti-DNP IgG-forming cells (plaque-forming cells, PFC) were counted 5 days after the start of cultivation. Note that treatment with some of the antibodies (2L2, 3L1, 7L114 and 148L4) resulted in complete loss of helper activity. Other monoclonal antibodies show variable degrees of effects on helper activity. b, Effect of monoclonal antibodies on the KLH-specific augmenting T cell (T₂). T cells of KLH-primed C3H mice were obtained by incubating the spleen cells in anti-mouse immunoglobulin-coated plastic dishes. They were then treated with monoclonal antibodies and complement, and the live cells were recovered by centrifugation on a layer of fetal calf serum. TaF was extracted from the cells by repeated freezing and thawing followed by ultracentrifugation at 40,000g for 1 h. The cell-free extracts corresponding to 3×10^6 original T cells were added to the test culture of DNP-KLH-primed spleen cells 2 days after the start of cultivation. This procedure was found to be suitable for detecting the TaF activity without much effect due to T₂F⁷. Anti-DNP IgG PFC were estimated 5 days after the onset of culture. Note that all monoclonal antibodies had an effect on the T_aF activity, except anti-Ia.2 which is specific for the B-cell Ia antigen. The suppression of the antibody response in some cases is probably due to the predominant suppressor effect after selective eliminat. on of augmenting T cells (see text).

subsets. We used two different methods: (1) the KLH-primed C3H ($H-2^k$) helper T cells were treated with monoclonal antibody and complement, and the cells were co-cultured with syngeneic B cells primed with a hapten, 2,4-dinitrophenyl (DNP), to examine the effects on carrier (KLH)-specific helper T cells; and (2) the KLH-primed splenic T cells were treated with monoclonal antibody and complement, and KLH-specific T_aF was extracted from the cells to assay residual T_aF activity by addition to the *in vitro* secondary anti-DNP antibody response.

Figure 1a illustrates the ability of some of the monoclonal antibodies to eliminate the helper activity of carrier-specific splenic T cells. Figure 1b demonstrates that many of these monoclonal antibodies are also effective in eliminating T_aFproducing cells. In some cases, the response was greatly suppressed, suggesting that the selective killing of T.F producer resulted in the predominance of remaining suppressor effects. A well-defined monoclonal antibody against a B-cell Ia antigen (anti-Ia.2) was found to be ineffective in eliminating both the helper and augmenting T cells. The ability of the monoclonal antibodies to remove helper and augmenting T cells did not always correlate; as some of the antibodies could kill only T₂F producer, there was an apparent reduction in the net helper activity as demonstrated in Fig. 1a. It was further confirmed that immunoadsorbents of at least three of the monoclonal antibodies (2L2, 3L1 and 14P) tested were able to absorb FL10derived T_aF (data not shown).

The results indicate that there exist I-region-encoded determinants expressed only on helper and augmenting T cells as detected by our monoclonal antibodies. These determinants seem entirely different from conventional Ia antigens of B cells and macrophages, as none of our monoclonal antibodies reacted with these cell types. It is of interest that the determinants are the products of genes mapped to the I-A subregion, the chromosomal segment which was defined originally by the presence of the Ir-1 gene¹ and later by the Ia-1 locus controlling the B-cell Ia antigen². As none of our antibodies react with B cells, we presume that the I-A subregion carries genes which are selectively expressed on augmenting and helper T cells. In addition, we have developed several hybridomas producing antibodies against at least three discrete molecules on suppressor and helper (T_{h2}) T cells controlled by genes in the adjacent I-J subregion (A. Kurata et al., unpublished results). Thus, we suggest that there exists a set of multiple loci tandemly arranged on the I-region chromosomal segment which is expressed only on mature functional T cells. As some of these I-region gene

Culture supernatants of two representative clones, 1L9 and 14P, were absorbed with various doses of spleen cells from strains of different haplotypes, and were tested for their residual cytotoxic activity against FL10. The results given here are those obtained by absorption with $1-5\times10^6$ cells for 100 μ l of culture supernatant. B cells were isolated from A/J spleen cells by treatment with anti-brain antiserum and complement. Note that absorption with $I-A^k$ spleen cells invariably eliminated the cytotoxicity of monoclonal antibodies for FL10, whereas spleen cells having a haplotype other than $I-A^k$ were unable to absorb the antibody activity. One other monoclonal antibody (21L27) cross-reacted with $H-2^b$. Some others showed cross-reactivity with $I-J^k$ and $I-E/C^k$ products; B10.A(3R) and B10.A(5R), as well as B10.A(4R), could absorb the anti-FL10 activity. These will be described elsewhere.

products on T cells were originally defined as a component of antigen-specific T-cell factors11, that is, putative antigen receptors of T cells, biochemical and genetic studies of the molecules reactive to our monoclonal antibodies are required to define the T-cell unit responsible for antigen recognition. Furthermore, our results cast new light on the organization and function of MHC in relation to the genetic regulation of various T-cell functions. The reagents described here should be useful for re-examining the antigen receptors of T cells and the molecular mechanism of MHC-restricted cell interactions.

We thank Drs K. Okumura and M. Taniguchi for criticisms, and Ms Yoko Yamaguchi and Taeko Fukuda for secretarial and technical assistance. This work was supported by a grant from the Ministry of Education, Culture and Science of Japan.

Structural homology of a macrophage differentiation antigen and an antigen involved in T-cell-mediated killing

Konrad Kürzinger, May-Kin Ho & Timothy A. Springer

Laboratory of Membrane Immunochemistry, Sidney Farber Cancer Institute, Harvard Medical School, Boston, Massachusetts 02115, USA

Two distinct murine cell-surface differentiation antigens, Mac-1 and LFA-1 (lymphocyte function-associated antigen 1), are compared here and shown to be related at the molecular level. Mac-1, defined by the M1/70 rat anti-mouse monoclonal antibody (MAb), is expressed on macrophages, natural killer cells and 50% of bone marrow cells, but not on B or T lymphocytes1-3. In contrast, the LFA-1 antigen, defined by the M7/14 rat anti-mouse MAb, is expressed on B and T lymphocytes and 75% of bone marrow cells, but not on thioglycollate-induced peritoneal exudate macrophages^{4,5}. MAb blocking studies suggest that LFA-1 participates in T-lymphocytemediated killing and T-lymphocyte antigen-specific responses^{4,5}. Mac-1 and LFA-1 have α-polypeptide chains of 170,000 and 180,000 molecular weight (M_r) , respectively, and both contain β polypeptides of 95,000 M_r . This similarity prompted us to investigate their relationship. Mac-1 and LFA-1 have distinct cellular distributions, MAb-defined antigenic determinants and α-subunits, but have highly homologous or identical β -subunits as shown by tryptic peptide mapping. Moreover, they share some common antigenic determinants recognized by a polyclonal antiserum. Cross-linking studies show that in each antigen the subunits are noncovalently associated in $\alpha_1\beta_1$ structures. Mac-1 and LFA-1 comprise a novel family of two-chain leukocyte differentiation antigens.

The distinct cellular distributions of the Mac-1 and LFA-1 antigens are emphasized by their reciprocal expression on

Fluorescence intensity (GF SRBC units)

Fig. 1 Reciprocal immunofluorescent labelling of peritoneal exudate cell macrophages and spleen cells by M1/70 and M7/14 MAb. Cells (50µl, 5×10⁷ ml in RPMI-1640, 5% fetal calf serum, 20 mM HEPES, 0.01 M NaN₃) were labelled with an equal volume of either M1/70 (a, b) or M7/14 (c, d) MAb-containing culture supernatants (dark dots) or NSI culture supernatant containing 50 μ g ml⁻¹ normal rat IgG as control (dim dots), washed, then labelled with affinity-purified fluorescein isothiocyanate rabbit F(ab')2 anti-rat IgG absorbed with mouse IgG. Immunofluorescence flow cytometry was performed on a Becton Dickinson FACS II equipped with a Nuclear Data log amplifier which was calibrated with glutaraldehyde-fixed sheep red blood cells (GF SRBC). Four-day thioglycollate-induced PEC (a, c) or spleen cells (d) were scatter gated to exclude red cells and lymphocytes, or red cells, respectively.

spleen cells and thioglycollate-induced peritoneal exudate cell macrophages (PEC) (Fig. 1). Spleen cells are >93% LFA-1 positive but only 6% Mac-1 positive, while exudate macrophages showed no significant LFA-1 expression but are >94% Mac-1 positive. Expression of Mac-1 and LFA-1 on 50 and 75% of bone marrow cells, respectively1,6, shows these antigens also have distinct myeloid distributions, and are co-expressed on a subpopulation of these cells.

Immunoprecipitation also confirmed that Mac-1 and LFA-1 are reciprocally expressed on concanavalin A-stimulated spleen

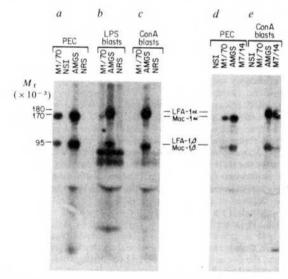

Fig. 2 SDS-PAGE of antigens precipitated from different cellular sources by M1/70 and M7/14 MAb and a polyclonal antiserum. Four-day Con A blasts (c, e), 4-day thioglycollate-induced PEC (>90% macrophages) (a, d) and LPS blasts (b) were prepared, surface labelled with 125 I, detergent solubilized, precleared, immunoprecipitated and subjected to SDS 5-15% gradient PAGE and autoradiography as previously described1,6. Two separate experiments (a-c and d, e) with independent cell preparations and SDS-PAGE were carried out. Cell lysates were immunoprecipitated with 25 or 50 μ l of NSI culture supernatant containing 50 μ g ml⁻¹ normal rat IgG (NSI) or 1 μ l of normal rat serum (NRS) as controls, 1 μ l of AMGS, 25 or 60 μl of M1/70 MAb supernatant (M1/70), or 20 μl of 1 mg ml⁻¹ M7/14 IgG (M7/14).

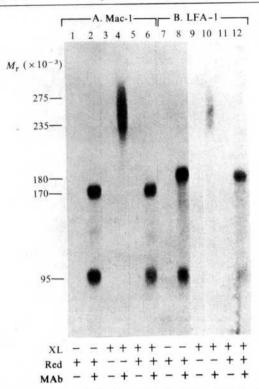

Fig. 3 Cross-linking of Mac-1 and LFA-1. PEC and EL-4 cells were surface labelled with ¹²⁵I using chloroglycoluril, and Triton X-100 cell lysates were prepared as previously described6, except haemoglobin carrier protein was omitted. Lysates were dialysed against 0.1 M NaCl, 0.05 M sodium borate, pH 9, and 800-μl aliquots were either mixed with 16 μl of dithiobis(succinimidyl propionate) (Pierce) dissolved in dimethylformamide, or not treated. After 1 h at 21 °C, samples were dialysed against two changes of 0.14 M NaCl, 0.05% NaN₃, 0.01 M Tris HCl pH 7.5. Aliquots were immunoprecipitated with antibodies coupled to Sepharose and subjected to SDS-5% PAGE and autoradiography as previously described6. a, precipitates from PEC with M1/70 MAb- or normal rat IgG-Sepharose. b, Precipitates from EL-4 with M17/4 MAb- (anti-LFA-1, Sanchez-Madrid et al., unpublished) or normal rat IgG-Sepharose. Samples were cross-linked (XL) and either reduced (Red) with 5% 2-mercaptoethanol or treated with 50 mM iodoacetamide before electrophoresis as indicated in the figure. Molecular weights were determined with standards as previously described6. Molecular weights >200,000 were determined by extrapolation and should be considered tentative. Crosslinked products were fuzzier than other bands, because the number and position of the cross-links formed affects hydrodynamic properties in SDS-

cells (Con A blasts) and PEC, and that the MAb do not cross-react between them. Thus, M1/70 but not M7/14 precipitated material from PEC (Fig. 2d), while M7/14 but not M1/70 precipitated material from Con A blasts (Fig. 2e). No cross-reaction between M1/70 and M7/14 could be detected, even when autoradiography was prolonged by a factor of five. This was as expected from the differing specificity of the MAb for cells (Fig. 1).

Despite these differences in cellular distribution and antigenic determinants recognized by MAb, Mac-1 and LFA-1 have strikingly similar two-chain structures. The LFA-1 α -chain is slightly higher in M_r than the Mac-1 α -chain, while the β -chains are identical in M_r (Fig. 2d, e). Determination of M_r by coelectrophoresis with standards in nongradient SDS gels at three different polyacrylamide percentages showed that the Mac-1 and LFA-1 α -chains are 170,000 and 180,000 M_r , respectively, and the β -chains 95,000 M_r (data not shown). The α - and β -chains are not disulphide linked^{1,6}.

Precipitation by MAb of two distinct polypeptide chains could be because both chains express the antigenic determinant, or because only one chain expresses the determinant but is non-covalently associated with the other chain. To investigate the quaternary structure of Mac-1 and LFA-1, cross-linking experiments were carried out. Detergent-solubilized lysates were cross-linked with the cleavable reagent dithiobis(suc-

cinimidyl propionate) and subjected to immunoprecipitation and SDS-polyacrylamide gel electrophoresis (PAGE) (Fig. 3). Instead of α - and β -chains (Fig. 3, lane 2), a cross-linked Mac-1 product of M_r 235,000–275,000 was found (Fig. 3, lane 4), in good agreement with the M_r of 265,000 predicted for an $\alpha_1\beta_1$ structure. Furthermore, the product was composed of α - and β -chains, as shown by reductive cleavage of the cross-links (Fig. 3, lane 6). A similar cross-linked product was obtained with LFA-1 (Fig. 3, lane 10). These results strongly suggest that both Mac-1 and LFA-1 contain α - and β -subunits which are noncovalently associated into $\alpha_1\beta_1$ quaternary structures.

One method of testing for structural homology between two proteins is by immunological cross-reactivity. MAb are not necessarily suitable, as they may recognize unique rather than shared antigenic determinants. Therefore, cross-reactivity was tested with a classical antiserum. A rat antiserum was raised against Mac-1 which had been partially purified from thioglycollate-induced macrophage membranes by L. culinaris lectin affinity chromatography and by MAb immunoadsorbent depletion of two other immunodominant antigens7. This antimacrophage glycoprotein serum (AMGS) potently precipitated Mac-1 and little or nothing else from PEC (Fig. 2a, d). The AMGS also precipitated large amounts of material from lipopolysaccharide-stimulated spleen cells (LPS blasts) and Con A blasts with an Mr identical to that of LFA-1, while this material was not precipitated by M1/70 (Fig. 2b, c). The material precipitated by AmGS from PEC and Con A blasts was shown to be identical to Mac-1 and LFA-1, respectively, by co-migration in SDS-PAGE (Fig. 2d, e), and by Cleveland peptide mapping (data not shown).

To determine whether precipitation of LFA-1 by AMGS was due to a true cross-reaction of anti-Mac-1 antibodies with LFA-1, or to the presence of antibodies with independent specificities in the AMGS, it was important to test whether the anti-LFA-1 activity could be absorbed with thioglycollate-elicited macrophages, which are Mac-1⁺ LFA-1⁻. Therefore, AMGS was absorbed with either macrophages or Con A blasts, and the amount of LFA-1 precipitated from Con A blasts was measured by quantitative scanning of autoradiograms (Fig. 4). Despite their lack of LFA-1 expression, macrophages gave

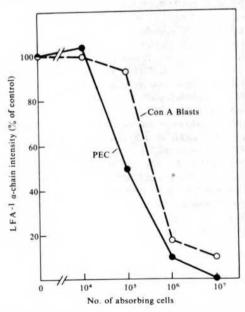

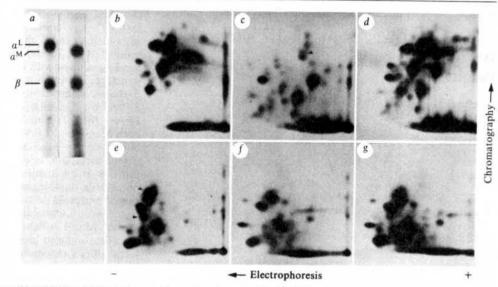

Fig. 4 Absorption by peritoneal exudate macrophages and Con A blasts of the ability of AMGS to precipitate LFA-1 from Con A blasts. AMGS (10 μl of a 1:100 dilution, which gave 70% maximal LFA-1 precipitation) was absorbed with PEC or Con A blasts in 100 μl of phosphate-buffered saline for 2 h at 4 °C. Cells were pelleted, and 80 μl of supernatant was used in indirect precipitation of 125 I-labelled Con A blast lysates and subjected to SDS-PAGE as described in Fig. 2 legend. After autoradiography with intensifying screens and hypersensitized Kodak XAR film, the film was scanned with a densitometer and LFA-1 α-chain was quantified as peak

Fig. 5 Tryptic peptide maps of SDS-PAGE purified LFA-1 and Mac-1 α - and β-subunits. LFA-1 and Mac-1 were purified from EL-4 and P388D, cells, as will be described in detail elsewhere. Briefly, EL-4 or P388D, detergent lysates in the presence of protease inhibitors were purified by affinity chromatography on M7/14 or M1/70 coupled to Sepharose CL-4B, respectively, and eluted with 20 mM glycine-NaOH, pH 10, or 20 mM triethanolamine, pH 11, respectively, in 0.5% Triton X-100, 1 mM phenylmethylsulphonyl fluoride. Eluates were neutralized and repurified by a second cycle of affinity chromatography. Purified antigens were concentrated and dialysed against phosphate-buffered saline, and 10-15 μg was iodinated in a volume of 100 μl with 1 mCi ¹²⁵I and 6 μg chloramine-T (ref. 10) for 1 min, followed by addition in sequence of $6 \mu l$ of $1 \text{ mg ml}^{-1} \text{ Na}_2 S_2 O_5$, $5 \mu l$ of 20 mg ml^{-1} KI and 5 μl of 20 mg ml⁻¹ bovine serum albumin. Rat IgG was also iodinated and treated in parallel as a control. After

dialysis, the α and β polypeptides were separated by SDS-7% PAGE and the wet gel was autoradiographed for 10 min (panel a). a, Lane 1, LFA-1; lane 2, Mac-1. dialysis, the α and β polypeptides were separated by SDS-1% PAGE and the wet get was autoradiographed for 10 min (panel a). a, Lane 1, LFA-1; lane 2, Mac-1. Bands were excised and digested with TPCK-trypsin as described by Elder et al. Peptide aliquots (5–8×10⁴ c.p.m. in 2–4 μ l) were spotted on 10×11.5 cm cellulose TLC plates (EM Laboratories). Electrophoresis was in 15% acetic acid, 5% formic acid, chromatography was in n-butanol/pyridine/acetic acid/water(65:50:10:40), followed by autoradiography. Comparison to the control rat IgG peptides showed that none of the spots were due to free 125 I or simple adducts. b, LFA-1 α-chain; c, Mac-1 α-chain; d, mixture of α-chains; e, LFa-1 β-chain; f, Mac-1 β-chain; g, mixture of β-chains. The arrows in b, c and d are explained in the text.

complete absorption. Furthermore, the macrophages were three-fold more effective than Con A blasts in absorbing anti-LFA-1 antibodies, showing absorption could not be attributed to contaminating lymphoid cells. The greater effectiveness of the macrophages was consistent with our previous findings that macrophages express 16×104 Mac-1 sites per cell while Con A blasts express 7.8 × 10⁴ LFA-1 sites per cell^{2.6}. It was concluded that antibodies to Mac-1 cross-react with LFA-1, and hence these molecules are structurally related.

The structural basis for this homology between Mac-1 and LFA-1 was investigated by peptide mapping. Mac-1 and LFA-1 were purified from the P388D1 macrophage tumour line and the EL-4 T-lymphoma line, respectively, by MAb affinity chromatography, and labelled with ^{125}I . The α - and β -subunits were separated by SDS-PAGE (Fig. 5a), excised from gels and subjected to peptide mapping. Tryptic peptide mapping showed the Mac-1 and LFA-1 β-subunits share at least 10 tyrosyl peptides, and are thus highly homologous or identical (Fig. 5e-g). One peptide unique to the LFA-1 β -subunit and one increased in intensity (arrows) may be due to carbohydrate processing differences between the EL-4 and P388D1 tumour lines, rather than to sequence differences. Cleveland peptide maps of LFA-1 and Mac-1 β -chains isolated from Con A blasts and PEC were identical.

The α -subunits had very different tyrosyl tryptic peptide maps (Fig. 5b-d). The α -chains from Mac-1 and LFA-1 showed 17 and 18 unique tryptic peptides, respectively. Co-migration of one peptide (marked by an arrow) was confirmed by a mixing experiment (Fig. 5d). These extensive differences strongly suggest that the Mac-1 and LFA-2 α-chains are products of distinct genes.

The large structural differences in the α -subunits suggest that the unique determinants recognized by the M1/70 and M7/14 MAb reside on these subunits. The β -subunits seem to be immunoprecipitated by virtue of their noncovalent association with the α -subunits. The α - and β -subunits do not appear structurally related, because they showed no tryptic peptide map identities. It seems likely that the common determinants on LFA-1 and Mac-1 revealed by polyclonal anti-Mac-1 antibodies are on the β -chain, although it is possible that the α -chains also cross-react. Definitive proof of where the determinants lie will require testing of antibodies on isolated chains.

Mac-1 and LFA-1 comprise a novel family of leukocyte differentiation antigens which contain noncovalently associated

a and β polypeptides of 170,000-180,000 M_r and 95,000 M_r . respectively. Alternative forms of the α polypeptide can be associated with a common or highly homologous β polypeptide in $\alpha_1\beta_1$ structures. Only two other two-chain leukocyte cellsurface antigen families have previously been described, the major histocompatibility antigens8 and immunoglobulins9. By analogy with these and other protein families such as the haemoglobins which have shared homologous or identical subunits, it seems likely that the Mac-1 and LFA-1 α -chains are also products of closely linked, homologous genes. The tryptic peptide differences in the α -subunits do not rule out homology, since amino acid sequence homologies of the order of 25-50% would be missed by peptide mapping. The selective expression of the Mac-1 and LFA-1 α-chains in the monocytic and lymphoid lineages is a particularly interesting feature of this differentiation antigen family. The structural relationships between these molecules suggest that the α - and β -chains may mediate specialized and general functions, respectively. LFA-1 plays an important part in antigen-specific T-lymphocytemediated killing of tumour cells and in T-helper cell responses4.5. Elucidation of the function of Mac-1 would provide a further comparison with LFA-1, and might provide important insights into the structure-function relationships of the α - and B-subunits.

Enhanced transformation of human fibroblasts by origin-defective simian virus 40

Michael B. Small*, Yakov Gluzman† & Harvey L. Ozer*

* Department of Biological Sciences, Hunter College, The City University of New York, New York, New York 10021, USA † Cold Spring Harbor Laboratory, Cold Spring Harbor, New York 11724, USA

Transformation of semipermissive human fibroblasts (HF) by wild-type simian virus 40 (SV40) or SV40 DNA is relatively inefficient compared with SV40 transformation of non-permissive rodent cells1. Whereas HF transformed with either SV40 or a subgenomic fragment of SV40 (that is incapable of making virions) containing the early region and the origin of DNA replication produce large amounts of free virus DNA2 lished human cell lines transformed by SV40 harbour defective virus genomes6 that are incapable of initiating virus DNA replication (M. Botchan, personal communication). We have now investigated whether the low efficiency of transformation is directly related to the ability of SV40 DNA to replicate autonomously in semipermissive HF. We have compared the efficiency of transformation of HF by origin-defective SV40 DNA (SV ori-) with that of other derivatives containing a functional viral origin of replication, using the calcium phosphate co-precipitation technique⁷. The transforming potential of SV ori mutants was found to be superior.

The SV ori mutant is a hybrid DNA consisting of plasmid (pMK16) and the full genome of SV40 DNA less 6 nucleotides at the BgII site^{8,9}. It is able to transform rat cells as efficiently as the ori SV40 derivative, but, unlike the latter, is able to transform permissive monkey cells¹⁰. The cell line chosen for the present studies was a human fibroblast designated HS74BM' (HF), which is derived from fetal bone marrow and displays a diploid human karyotype¹¹. This cell line is semipermissive for SV40, producing virus at an efficiency of ~1% that of permissive monkey kidney fibroblasts¹². It has been shown to be transformable by DNA transfection with an early region fragment of SV40, albeit at a low frequency⁵.

Initial experiments revealed that the SV ori recombinant molecule was capable of transforming HS74 as assayed by focus formation in monolayer and colony formation in soft agarose ('anchorage independence'). Transformed colonies express T antigen as detected by immunofluorescence. The actin cable organization of these transformants was consistent with typical SV40 transformants (R. Pollack, personal communication).

Direct quantitative comparison among intact superhelical form I SV40 DNA, plasmid SV ori⁺, plasmid SV ori⁻, as well as among linear form III plasmid SV ori⁺ and plasmid SV ori⁻ is shown in Table 1. Figure 1 shows typical foci. pSV ori⁻ DNA was most efficient in both transformation assays (focus formation and anchorage independence) as well as in the different protocols used after DNA transfection (see Table 1 legend). The results are most striking for the anchorage independence assay, which is considered the more stringent *in vitro* transformation assay¹³. It is also the most stringent for cell viability because it requires colony formation.

This finding strongly suggested that the absence of a functional origin of replication in SV ori⁻ resulted in its enhanced transformation efficiency. However, as plasmid SV ori⁺ DNA had a higher transforming potential than did virion DNA, other possibilities were considered. First, the improved efficiency might be solely due to the presence of adjoining plasmid sequences and/or modification of DNA through propagation in a bacterial host¹⁴. As shown in Table 2, we compared the efficiency of transformation by linearized virion DNA with linear viral DNAs derived from pSV ori⁺ and pSV ori⁻, from which plasmid DNA was removed (lines 1, 3, 4). Again SV ori⁻ was the most efficient. Residual contribution from the bacterial

SV40 virion form I DNA was extracted from SV40-infected monkey kidney cells (CV-1) by the technique of Hirt¹⁸ and isolated by CsCl-EtBr equilibrium centrifugation¹⁹. The DNA was further purified by deproteinization with redistilled phenol/CHCl₃/isoamyl alcohol, precipitated in 2 volumes 95% ethanol, redissolved in TE buffer (10 mM Tris-HCl pH 7.5, 1 mM EDTA) and stored at 4 °C before use. pSV ori* and pSV ori¬ plasmid DNAs were isolated from Escherichia coli χ1776 by the clear lysate technique²⁰ and purified as described above. Form III derivatives were prepared by digestion of form I with XhoI (which makes a single cut within pMK16); DNA was deproteinized and reisolated after ethanol precipitation. HS74 were utilized at the eighth passage. Culture medium was a 1:1 mixture of Dulbecco's modified Eagles medium (DMEM) and Ham's F-10 (MABioproducts) supplemented with 15% fetal calf serum ("complete media"), unless otherwise noted. Cells were grown in a 5% CO₂ atmosphere at 37 °C. DNA transfections were performed essentially as described by Wigler et al.²¹: 20 h before transfection, cells were plated at 7.5 × 10⁵ per 60 mm Petri dish. Cultures were refed 4 h before transfection with 4.5 ml of DMEM supplemented with 5% calf serum. DNA-calcium phosphate precipitates were prepared such that each dish received 0.5 ml containing 0.5 μg SV40 genome equivalents and 20 μg high molecular weight salmon sperm DNA (as carrier). Cells were exposed to DNA for 4 h, then refed with complete medium. Cultures were incubated for 3 weeks and scored for transformed foci (in situ selection). In the subculture protocol, cultures were trypsinized 3 and 7 days post-transfection; one-half of each dish was reseeded into a 100 mm Petri dish and scored 3 weeks later for focus formation; the other half was suspended in 0.35% agarose⁵, and scored after 3 weeks for macroscopic colonies 0.1 mm in diameter).

* Data presented as average number of foci or colonies per plate, with individual points in parentheses.

SV40 virion form I DNA was extracted from SV40-infected monkey kidney cells as described in Table 1 legend. Virion form III DNA was generated by digestion of form I DNA with BamHI. The subgenomic Eco/Bam fragment was isolated by simultaneous digestion of virion form I DNA with EcoRI and BamHI; the DNA was then electrophoresed on a 1% preparative agarose gel in Tris-borate buffer at 25 V for 18 h. DNA was visualized under UV light by ethicium bromide staining; and the 4,670 base pair fragment was cut out from the gel and reisolated by electroelution²². pSV ori and pSV ori plasmids were isolated as described in Table 1 legend. SV ori and SV ori form III DNAs (viral sequences from which plasmid sequences were removed) were generated by digestion of form I plasmid DNA with BamHI, which separates SV40 from pMK16 sequences; viral DNA was isolated by agarose electrophoresis and electroelution as above. Cell culture, DNA transfections and all transformation assays were performed as described in Table 1 legend. Restriction enzyme digests were performed according to suppliers' (New England Biolabs and Bethesda Research Labs) specifications.

environment (such as methylation) appears likely as well because SV ori+ form III transforms with higher efficiency than viral DNA isolated from permissive monkey cells. Note, however, that the contribution of bacterial modification seems to be transient, and almost completely disappears after 7 days (see Tables 1, 2). Second, we tested whether secondary infection was responsible for the reduced transformation efficiency of viral DNA by using a viral DNA molecule which had been deleted of 750 base pairs in the late region, precluding formation of viral particles 15,16. No improvement was observed (compare lines 1 and 2 in Table 2).

These experiments demonstrate that the efficiency of transformation of semipermissive human fibroblasts can be markedly increased by using a viral DNA which is defective at the origin of DNA replication. Transformation with SV40 ori- mutants resulted in an increased number of transformants as observed by both direct assay (for example, in situ) and subculture assays for anchorage independence. Furthermore, foci and agarose colonies generated with pSV ori DNA were larger than those generated by SV40 derivatives containing a functional viral origin of replication (see Fig. 1). The transformation frequency can be further increased by using linearized pSV ori DNA which gives markedly better results than conventional viral DNA I. The frequency of transformation of HF by pSV ori DNA increases as a function of the amount of DNA used in transfection. However, this increase is non-linear, and approximating threefold over the range 1-10 µg per culture. Increasing the amount of SV40 virion DNA in the same manner does not substantially influence the transformation frequency (data not shown). We are now investigating whether HF transformed by SV ori DNA are more likely to become permanently established¹⁷. Preliminary Southern blot analysis of the Hirt (low molecular weight DNA) supernatants of transformants generated by various SV40 derivatives has failed to detect production of free SV40 viral DNA in SV ori -- derived transformants, as predicted (D. Neufeld and H. Ozer, unpublished results).

In conclusion, we believe that the origin-defective recombinant SV40 molecule is the vector of choice for SV40 transformation of human fibroblasts. Its enhanced transformation efficiency (relative to wild-type SV40) is probably due to its inability to excise and replicate in transformed semipermissive cells. This property should increase the stability of the transformed phenotype. Furthermore, it precludes the possibility of cell death mediated by uncontrolled viral DNA synthesis or production of virus particles. We observe that SV ori DNA linearized in its plasmid sequence by digestion with the restriction enzyme XhoI routinely gives the highest transformation frequencies (~1 in 105 or greater can be obtained on transfection of early passage cells). Transformants of human fibroblasts generated by this vector may prove particularly useful in the establishment of human cell lines for various purposes.

We thank Ms Ruth Kalmanowitz for technical assistance, Dr Krishna K. Jha for helpful discussions, and Drs Richard Frisque and James Stringer for critical reading of the manuscript. This work was supported by NIH grants CA 23002 and CA 23003 (H.L.O.) and CA 13106 (Y.G.). The HS74BM cells were provided by the Cell Culture Laboratory, Naval Biochemical Research Laboratory, Oakland, California, under contract E-73-2001-NO1 within the NIH Special Virus-Cancer Program.

Enhanced metastasis of tumours induced by a SV40 small T deletion mutant

K. Dixon*, B.-J. Ryder & E. Burch-Jaffe†

Department of Biological Chemistry and The Molecular Biology Institute, University of California, Los Angeles, California 90024, USA

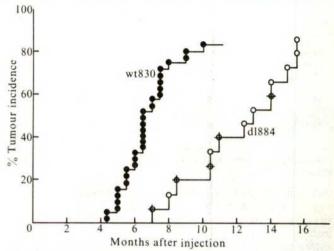

The lethality of tumours is determined largely by their ability to metastasize to distant sites. Once metastasis has occurred, eradication of the tumour cells from the body becomes difficult or impossible. Although the steps involved in tumour metastasis have been well documented (for review see refs 1-3), the cellular parameters that influence the tendency of tumours to metastasize have been more difficult to define 4-7, and the underlying genetic determinants of metastatic potential are not known. We are studying the metastasis of tumours induced in hamsters by simian virus 40 (SV40). We show here that tumours induced by a viral mutant (d1884) in the small T antigen gene tend to metastasize, whereas tumours induced by wild-type SV40 rarely do so. Thus, we have a well defined system in which the underlying genetic differences in the transforming viruses are known and in which we may be able to correlate these differences with cellular parameters that determine tumour metastasis.

Present address: Department of Human Genetics, University of Washington, Seattle, Washington 98195, USA

Fig. 1 Time course of tumour induction by wild-type SV40 (wt830) and the small T deletion mutant (d1884). Newborn <24 h of age) Golden Syrian hamsters (strain LVG, Charles River) were injected subcutaneously between the shoulder blades with $\sim 1 \times 10^8$ plaque-forming units (PFU) of either viral strain. (The small T deletion mutant d1884, constructed from the parental strain wt830 by Shenk *et al.*¹⁶, eliminates 253 base pairs¹⁷ in the 0.54-0.59 map unit segment of the early region of SV40. Thus, the coding sequence for the C-terminal 63 amino acids of the 174 amino acid small T protein are deleted. The coding sequences for the large T protein remain intact.) Animals were palpated for tumours at least once per week and the age of the animal at the time the tumour was first observed was recorded. The 'latency period', or the time required for the tumour to become observable, is plotted on the abscissa. Thirty animals were in the group injected with wild-type virus and 15 were in the group injected with the mutant virus. Animals displaying metastases are indicated by the crossed symbols.

We first compared the ability of wild-type SV40 (wt830) and the small T deletion mutant (d1884) to induce tumours following subcutaneous injection in newborn hamsters. The d1884 mutant is deficient in transformation of rodent cells in culture in some conditions⁸⁻¹⁰ and it was shown to cause tumours in animals at reduced frequency^{11,12}. We found that d1884 induces tumours at a similar frequency to wild-type SV40 but that these tumours appear after a longer latency period (Fig. 1)—a median latency period of 12.5 months, compared with 6.5 months for wild-type virus. The most striking finding, however, was that some of the animals injected with the d1884 virus (indicated by crosses in Fig. 1) developed tumour foci at sites distant from

the subcutaneous injection site. In some cases tumour foci were found only on internal organs or in the abdominal cavity, whereas in others both subcutaneous tumours and distant tumour foci were present (see Table 1). In all cases histological examination showed the neoplastic cells in the tumours and organs to be fibrosarcomas.

Of 36 animals injected with wt830, 30 animals developed tumours. The tissues of 12 animals with wild type-induced tumours were examined macroscopically and histologically and no abdominal tumours or metastases were observed.

To prove that the subcutaneous tumours and distant tumour foci actually arose from d1884-transformed cells, we have

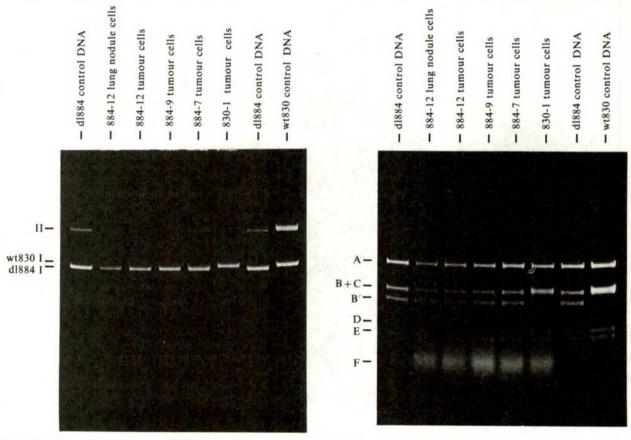

Fig. 2 Agarose gel electrophoresis of DNA from virus rescued from SV40-induced tumours. Tumours were removed from the animals and cell lines established by disaggregation of tumour pieces with collagenase and culture in minimal essential Eagle's medium with Earles salts, 5% fetal calf serum and 5% calf serum. Virus was rescued from these cell lines by culturing them together with permissive CV-1 cells (African green monkey kidney line CV-1 clone TC 7; ref. 18). Virus was collected after 14 days and used to infect more CV-1 cells. After 3 days the viral DNA was extracted from these cells by the method of Hirt¹⁹. The extracted DNA was electrophoresed on 0.8% agarose gels or cleaved with HindIII (New England Biolabs) and then electrophoresed. The direction of migration is from top to bottom in the photograph. Left panel, uncleaved viral DNA; right panel, viral DNA cleaved with HindIII. The numbers above designate individual animals. Roman numerals to the side refer to SV40 form I and II molecules. Letters to the side refer to the HindIII restriction fragments. The mutant d1884 deletion is within fragment B.

Table 1 Characteristics of hamsters exhibiting metastases

Animal	Site of principle tumour	Time at which hamster died or was killed	Location of metastases
884-1 884-2 884-5 884-6 884-9	None Abdominal None Abdominal Subcutaneous, abdominal	Died at 8.5 months Died at 7 months Died at 10.5 months Died at 11 months Killed at 14 months (14 days after subcutaneous tumour was observed)	Lung, spleen Peritoneum, lung Liver, pancreas, colon and lymph node Spleen, liver and intestine Peritoneum, diaphragm, liver
004-12	Subcutaneous	Killed at 11 months (45 days after subcutaneous tumour was observed)	Pleural surface

Animals were necropsied as soon as possible after death or immediately after killing. Gross observations were made and tissues prepared for histology.

characterized virus rescued from cultured tumour cells by cocultivation with permissive monkey cells (CV-1 line). Rescued virus was used to infect CV-1 cells and viral DNA was prepared from a Hirt supernatant fraction. Cleaved (*HindIII*) and uncleaved viral DNA was electrophoresed on 1% agarose gels, stained with ethidium bromide and photographed (Fig. 2). Viral DNA rescued from d1884-induced tumour cells co-electrophoreses with d1884 viral DNA; viral DNA rescued from wt830-induced tumour cells co-electrophoreses with wt830 viral DNA. Note that d1884 viral DNA was rescued from cells recovered from a metastatic lung nodule as well as from the subcutaneous primary tumour.

The distant tumour foci that we observed arose either as metastases from a primary tumour or by independent virusmediated transforming events. These two possibilities may be distinguished by comparing the viral genome integration patterns in cells from the primary tumours with those in cells from the distant tumour foci. If the distant tumour foci arose by independent transforming events, the viral genome integration patterns would be likely to differ from those of the primary tumour, because SV40 viral DNA seems to integrate at random^{13,14}. If these distant tumour foci are metastases from the primary tumour, their viral integration patterns should be the same.

We analysed the viral genome integration patterns from primary tumours and metastases. Cellular DNA was extracted from cultured tumour cells, treated with restriction endonucleases, electrophoresed on agarose gels, transferred to nitrocellulose sheets¹³ and hybridized with the ³²P-labelled nick-translated SV40 DNA probe¹⁴. Analysis of the integration patterns in cultured cells from several of the primary subcutaneous tumours, using restriction enzymes that cut within the SV40

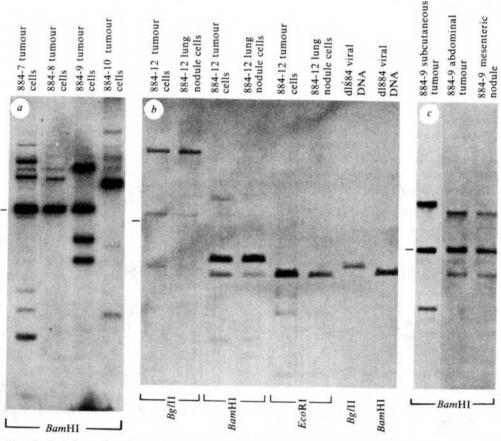

Fig. 3 Hybridization of restriction endonuclease-cleaved cellular DNA from small T deletion mutant-induced tumours and metastases with the SV40 probe. Cellular DNA was extracted from cultured tumour cells by the method of Botchan et al.²⁰ or from frozen tumour pieces as described by Blin and Stafford²¹. DNA was then cleaved with BamHI, Bg/II or EcoRI (New England Biolabs) and electrophoresed on a 0.8% agrose gel. DNA was transferred to nitrocellulose (as described by Botchan et al.¹³) and hybridized with ³²P-labelled nick-translated SV40 DNA (~1×10⁸ c.p.m. per μg) according to the method of Wahl et al.¹⁴. The position of the unit length linear SV40 band is indicated by the dashes in the figure. a, Cellular DNA was prepared from cultured cells derived from primary tumours of four different animals. b, Cellular DNA was prepared from cultured cells derived from a primary tumour and a lung nodule from the same animal. (The Bg/II enzyme preparation contains a nicking activity that converts SV40 form I DNA to form II.) c, Cellular DNA was extracted from frozen tumour pieces of three separate tumours present in a single animal.

Table 2 Metastasis of re-injected tumour cells

Tumour cells	No. of cells inoculated	Tumour incidence	Tumour latency [median (range), in days]	Metastasis incidence
884-12 884-12 830-1 830-1	3×10^{4} 3×10^{3} 3×10^{4} 3×10^{3}	4/4 5/5 5/5 3/5	25(25–30) 30(25–37) 30(25–92) 81(49–91)	4/4 5/5 1/5 0/5

Tumour cells were passed in culture, then trypsinized and injected subcutaneously into 7-week old hamsters. Animals were killed and examined for metastases ~42 days after the subcutaneous tumours were first observed.

genome either once or not at all, indicated that the integration patterns are relatively simple (only a few integration sites) and that there is a small amount of free viral DNA. Furthermore, we found a unique pattern in each of the cell lines derived from subcutaneous tumours in different animals (Fig. 3a). Most importantly, we found that the integration pattern in cells from a primary tumour and lung nodules from the same animal are identical (Fig. 3b). Thus, we conclude that the cells in the lung tumour nodules are actually derived by metastasis from the subcutaneous primary tumour. However, not all of the distant tumour foci seem to be derived as metastases from a subcutaneous tumour. For example, one animal had a subcutaneous tumour and an abdominal tumour exhibiting distinct viral integration patterns (Fig. 3c). Additional small abdominal tumour foci had patterns identical to the major abdominal tumour (Fig. 3c). Thus, either the abdominal tumours were derived as metastases from an undetected subpopulation of cells in the subcutaneous tumour or they arose from an independent transforming event perhaps occurring in the abdomen. We never observed abdominal tumours following subcutaneous injection of the wild-type virus. If the development of the abdominal tumours is unrelated to metastasis, it could be due to a change in the cell specificity of the virus particle itself.

What causes the difference in metastasis of tumours induced by wild-type SV40 and the small T deletion mutant? We believe that the observed metastasis is not a result of the increased latency period exhibited by the small T deletion mutant. Metastatic tumours arose after latency periods similar to non-metastatic tumours observed in many of the animals injected with the wild-type virus. Furthermore, it is unlikely that the metastasis is due to a prolonged presence of the primary tumour in the animal. Deichman and Kluchareva¹⁵ showed that metastasis of wild type-induced tumours sometimes occurred when tumours were allowed to develop for more than 60 days after they had first appeared; in our experiments, animals were usually killed at much earlier times after the tumours first appeared because later on the tumours become quite large and the animals appeared sickly. Instead, the tumour metastasis seems to be related to properties of the tumour cells themselves. We have determined that cells derived from metastatic tumours and passed in culture retain their ability to metastasize on reinjection in adult animals; cells from wild type-induced tumours metastasize less readily in these conditions (Table 2). Topp et al. 12 compared cells derived from wild type- and small T mutant-induced tumours for certain transformed properties (the ability to grow suspended in methylcellulose, loss of actincontaining cable networks and synthesis of plasminogen activator). Although no differences between the wild type- and mutant-induced tumour cells were observed, metastasis was not monitored in their studies, and it is unclear whether any of the cell lines analysed were derived from metastatic tumours.

Further analysis of the properties of our tumour-derived cell lines may reveal characteristics which explain their difference in metastatic potential. Once these characteristics have been identified, we will be able to investigate how they are determined by the genetic make-up of the transforming viruses.

This research was supported by seed money research grants from California Institute for Cancer Research and Cancer Research Coordinating Committee. Activation of non-expressed bovine papilloma virus genomes by tumour promoters

Eberhard Amtmann & Gerhard Sauer

Institute for Virus Research, German Cancer Research Center, 6900 Heidelberg, FRG

Naturally occurring cancer seems to be a multiple-hit phenomenon resulting from the interaction of several factors. Numerous environmental carcinogens on one hand and the widespread tumour viruses on the other, are capable of either transforming cells in vitro or inducing tumours in vivo. A few years ago, based on epidemiological evidence, a possible interaction between bovine papilloma viruses and an environmental carcinogen in bracken fern was noted in conjunction with alimentary cancer in cattle1. We report here that tumour-promoting agents which by themselves are unable to transform cells, are capable of inducing the transcription of bovine papilloma virus type 1 (BPV-1) in mouse embryo fibroblast (MEF) tissue cultures, where the viral genomes reside in a non-expressed episomal state after infection. In such cells, one brief treatment with the tumour promoter results in the transcription of the same viral mRNA species present in BPV-1-induced tumours and in BPV-1-transformed cells. Furthermore, viral DNA is replicated and the cells acquire the transformed phenotype. Once activated, these properties remain stable. This interaction between tumour promoters and latent inactive tumour virus genomes leads, in appropriate cell systems, to the activation of particular viral genes and to the transformed phenotype of the host cells.

BPV can induce fibroblastic tumours in animals²⁻⁴ and is able to transform tissue culture cells^{5,6}. Unlike most other tumour viruses, however, BPV achieves transformation as an unintegrated episome⁷⁻¹². A further peculiarity of BPV is the lack of a permissive tissue culture system. Virion production occurs exclusively in the differentiated periphery of the virus-induced warts¹³. Hence, as a rule, infection of tissue culture cells leads, if at all, to only a partial expression of the viral genome¹⁴ with ensuing transformation. Not all tissue isolates from one species are transformable; only 2 of 11 fetal bovine skin cultures could be transformed with BPV¹⁵. Similarly, not all mouse-derived

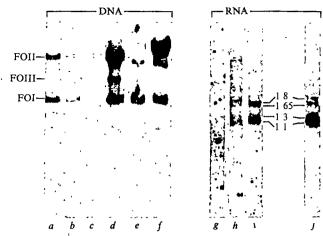

Fig. 1 Effect of TPA on BPV-1-infected MEF cells MEF cells (DBA strain, passage 5) were infected with a BPV-1 virus pool (0 5 ml per 10 which had been prepared as follows a bovine wart was minced in an Omnimix at 4 °C for 10 min (10% w/v in phosphate-buffered saline). After pelleting at 20,000g for 20 min, the virus-containing supernatant was sterilized by passage through a Millipore filter and used to infect MEF cells. The viral DNA showed a typical BPV-1 restriction enzyme cleavage pattern The infected cells were passaged once a week at a 1.5 split ratio in Eagle's basal medium supplemented with 10% fetal bovine serum DNA and RNA were prepared 4 days after plating when the cells had reached confluence, and were analysed by gel electrophoresis either in 1% or 14% agarose as described elsewhere²² After phenol extraction, the RNA was selectively After phenol extraction, the RNA was selectively precipitated with 2 M LiCl and traces of DNA were removed by treatment with DNase I (grade I) as detailed elsewhere Transfer to mitrocellulose filters, hybridization with a nick-translated ³²P-labelled BPV-1 DNA probe (cloned in pBR322 and provided by P Howley), and autoradiography were as described elsewhere 22 In each track of the gels 5 μ g of DNA and 20 μ g of RNA were assayed a-f, DNA from BPV-1-infected MEF cells a-c, 1, 2 and 3 passages, respectively, after infection, d, same as a, but exposed for 4 days to 10⁻⁷ M TPA; e, same as d, but in the first passage after removal of TPA, f, same as d, but in the fifth passage after removal of TPA. g-1, RNA from the same cultures as above. g, MEF cells 1 passage after infection; h, 1 passage after infection and exposure for 4 days to 10^{-7} M TPA, l, same as h, but in the second passage after removal of TPA; , RNA from BPV-1-transformed hamster embryo fibroblast cells in the 16th passage after infection. The values on the right indicate the sizes of the BPV-1 RNA sequences14 in kb

fibroblast tissue cultures could be transformed, for example, NIH 3T3 and C 127 responded to BPV-1 infection with transformation⁸, while repeated efforts in our laboratory to transform fibroblasts from the DBA strain were unsuccessful.

Following passaging of the BPV-1-infected phenotypically normal cells, the viral DNA is eventually lost because of its failure to replicate. This is shown in Fig. 1a–c, where the method of Southern¹⁶ was used to reveal BPV-1 DNA after infection of MEF cells with BPV-1 virions. One passage after infection, superhelical form I (FOI) and relaxed FOII BPV-1 DNA were detected in the cells using a 32 P-labelled, nick-translated BPV-1 DNA probe. After the second passage, most of the viral DNA had disappeared (Fig. 1b), and after a third passage no viral DNA was detectable (Fig. 1c). It has been shown that 12-O-tetradecanoylphorbol-13-acetate (TPA) has a stimulatory effect

on Epstein-Barr virus¹⁷ and episomal papovavirus genomes¹⁸ and this is confirmed in Fig. 1d. A parallel culture to that shown in Fig. 1a was subjected to TPA treatment and, when examined 4 days later displayed considerably more BPV-1 DNA, particularly FOII and some unit-length FOIII. This effect was observed as early as 18 h after treatment with TPA. Even when administered to cells in the third passage after infection, TPA amplified the minute amounts of persisting non-detectable BPV-1 DNA (see Fig. 1c) to the extent that a clearly visible signal was obtained by the Southern method (data not shown)

Furthermore, the BPV-1 DNA continues to replicate in the absence of TPA. Figure 1e, f show the viral DNA content at one and five passages after TPA removal. In addition to FOI and FOII, multimeric BPV-1 DNA structures are present. These car be converted to linear FOIII after cleavage with single-currestriction endonucleases (data not shown).

The effect of TPA on viral transcription is shown in denaturing gels (Fig. 1g-j)¹⁹. The total RNA was extracted from the same cultures used to analyse DNA. Although untreated MEI cultures contain BPV-1 DNA one passage after infection (Fig 1a), no viral RNA sequences could be detected (Fig. 1g) However, in a parallel culture, 4 days after TPA treatment (Fig 1h; see Fig. 1d for the DNA content), several species of BPV-RNA were found. The same RNA species are also found in the polyadenylated RNA of BPV-1-induced hamster tumours and BPV-1-transformed hamster cells¹⁴ (Fig. 1j). That these bands represent true RNA sequences is shown by their absence after RNase or alkali treatment (data not shown). Viral transcription persisted during subsequent passages in the absence of TPA (Fig. 1i). In agreement with our previous findings, the 2-kilobase (kb) mRNA which probably encodes the viral capsid protein and which is present exclusively in the permissive periphery of the warts¹⁴, was absent. The faint larger bands were observed only occasionally and may represent mRNA precursors.

Together with the induction of viral transcripts, TPA also induced morphological alterations of the cells. We observed a saturation density 25% higher than the control (uninfected TPA-treated) or infected (untreated) cultures 6 days after temporary TPA treatment (18 h). Furthermore, severa passages after TPA treatment, the BPV-1-infected cultures had acquired the ability to form colonies in medium having low serum content. This transformed phenotype was not evident in control cells.

We obtained similar results with a newly developed compound, 12-O-retinoylphorbol-13-acetate (RPA)²⁰, which combines the anti-promoting vitamin A with a phorbol este tumour promoter. RPA exerts a mitogenic effect on the skin o NMRI mice similar to that induced by TPA. When applied to BPV-1-infected MEF tissue culture cells, RPA activated the latent non-expressed viral genomes in a manner similar to TPA (Table 1).

However, not all cell lines provide a suitable environment for the above interactions (Table 1). While primate cells did no respond at all, a temporary activation of BPV-1 DNA replication in the absence of transcription was achieved by TPA

Table 1 Effect of TPA and RPA on BPV-1 episomes						
Cell type	Designation	DNA replication	Transcription	Transformation		
Monkey kidney	CV-1	-		_		
Human foreskin fibroblasts	HFF	_	_	_		
Human embryonic lung	HEL		~	_		
Bovine kidney	NBL	Transient	_	_		
Bovine fetal thyroid	BFT (ref. 21)	+	Transient	Transient		
Rat embryo fibroblast	REF	Transient	_	-		
Mouse embryo fibroblast	MEF*	+	+	+		

DNA replication and transcription were determined by the method of Southern¹⁶ 4 days after addition of 10⁻⁷ M TPA or RPA. Both compounds were applied separately to all cell types. Transformation reduced serum requirement and increased saturation density. –, No effect observed. 'Transient' denotes that the effect was abolished after two passages following TPA or RPA treatment. +, BPV-1 DNA replicates in the absence of tumour promoters.

^{*}DBA mouse strain, fifth passage; cells show a limited in vitro lifetime unless infected and treated with either TPA or RPA.

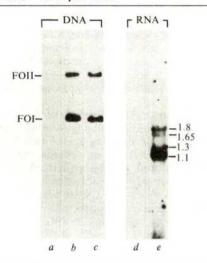

Fig. 2 Effect of RPA on BPV-1-infected BFT cells. BFT cells were infected with BPV-1 and passaged as described in Fig. 1 legend. Preparation and characterization of BPV-1-specific DNA and RNA sequences are also described in Fig. 1 legend. a-c, DNA from BFT cells. a, Uninfected; b, four passages after infection; c, as in b, but treated for 3 days with RPA (10^{-7} M) ; d, RNA from the same culture as in b; e, RNA from the same culture as in c. The values indicate the sizes of the BPV-1 RNA sequences in kb.

treatment of NBL cells. BFT cells, also of bovine origin, which are free of endogenous BPV-1 genomes (Fig. 2a), when infected with BPV-1 were capable of supporting the continuous replication of episomal BPV-1 DNA (Fig. 2b). However, no viral transcripts were observed (Fig. 2d) and a normal phenotype was retained. After exposure to RPA (or TPA, data not shown), no additional effect on the BPV-1 DNA content was observed (Fig. 2c), but transcription of the BPV-1 genomes was initiated (Fig. 2e) and the cells acquired a transformed phenotype (Fig. 3). However, these effects were transient, as transcription of the BPV-1 episomes was abolished after two further passages in the absence of promoter, despite the continuing replication of BPV-1 DNA. It is interesting that the relative amounts of BPV-1 transcripts obtained after RPA (and TPA) treatment corresponded initially to, or even exceeded those observed in BPV-1-transformed hamster embryo fibroblast (HEF) cells (Fig. 1j) which contain comparable numbers of episomal DNA, that is, ~50-100 per cell. Treatment with the tumour promoters failed to enhance the relative amount of BPV-1-specific transcripts in the latter case (not shown).

Thus, it seems that the promoter-treated BFT and MEF cells may constitute an appropriate host system for amplification and expression of foreign genes which have been inserted into a BPV-1 vector. Furthermore, the experimental system described here may be used for rapid screening of putative tumourpromoting agents, thereby reducing the need for time-consuming studies in laboratory animals.

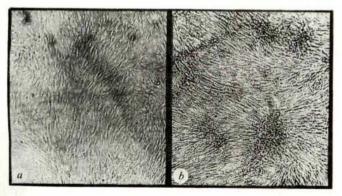

Fig. 3 Effect of RPA on BFT cells. BPV-1-infected cells (0.1 ml BPV-1 per 2×106 cells) were passaged (1:5 split ratio) 4 days after infection: a, 7 days after passaging in medium without RPA; b, parallel culture, but maintained for 7 days in medium containing 10⁻⁷ M RPA.

This work was supported by the Bundesminister für Forschung und Technologie. We thank Drs G. Fürstenberger, D. Berry, B. Sorg and F. Marks for the RPA, Dr E. Hecker for the TPA, and G. P. Gray for help in preparation of the manuscript.

Electron microscopy of hepatitis B core antigen synthesized in E. coli

B. J. Cohen & J. E. Richmond

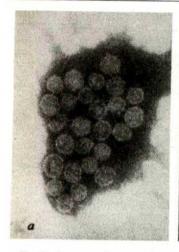

Virus Reference Laboratory, Central Public Health Laboratory, 175 Colindale Avenue, London NW9 5HT, UK

DNA fragments from hepatitis B virus (HBV) have been inserted into plasmid vectors and cloned in Escherichia coli¹, and some of these bacterial clones have been reported to synthesize hepatitis B core antigen (HBcAg)1,2. Material from a derivative of one HBcAg-synthesizing clone is being evaluated in our laboratory and elsewhere^{3,4} as a serological reagent for use in various assays, including immune electron microscopy, to detect anti-HBcAg antibody. It has been shown by gel exclusion chromatography that the bacterial HBcAg is in an aggregated form3. We now report that the E. coli HBcAg preparation contains small round particles similar in appearance to the viral cores previously seen in material obtained from HBV-infected humans⁵⁻⁷ and chimpanzees⁸.

Extracts of E. coli harbouring the recombinant plasmid pRI-11 (ref. 3) and of human liver containing HBcAg were examined by immune electron microscopy (Fig. 1). The morphology of particles precipitated by anti-HBcAg antibody from the bacterial HBcAg preparation was similar to that of viral cores seen in extracts from HBV-infected liver. The average diameter of the particles from E. coli was 27.3 nm (range 24-31 nm, n = 100); that of particles in the liver extract was 28.1 nm (range 24–32 nm, n = 100).

Preliminary density gradient studies have shown that the E. coli- and liver-derived HBcAgs give bands at 1.35-1.36 g ml in caesium chloride, indicating that they contain nucleic acid; this was confirmed by the UV absorption spectra of both antigens (P. Wingfield and K. Murray, personal communication).

Further immune electron microscopy tests have confirmed that the particles seen in the E. coli preparation possess the characteristic antigenic properties of HBcAg. Results of these studies and of other confirmatory tests will be reported elsewhere.

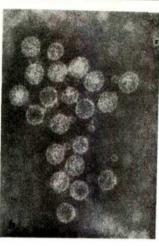

Fig. 1 Immune electron microscopy of a, E. coli-derived and b, human liver-derived HBcAg (×189,000). Each antigen (0.1 ml) was mixed with an equal volume of human anti-HBcAg IgG (2-400 µg ml⁻¹), incubated at 20 °C for 1 h, then diluted to 2.5 ml with phosphate-buffered saline and centrifuged at 48,000g for 1 h. The resulting pellet was resuspended in the minimum amount of distilled water (<0.1 ml) and mixed with an equal volume of negative stain (3% phosphotungstic acid, pH 6.3). A drop of the mixture was placed on a Formvar-carbon-coated grid which was then blotted dry with filter paper. The specimens were examined in an AEI 801 or a Jeol 100 CX electron microscope with magnifications calibrated using crystalline catalase

Electron microscopy has thus revealed the presence of small round particles in extracts of E. coli that carry a hybrid plasmid directing the synthesis of HBcAg. The morphological and antigenic properties of these bacterial HBcAg particles are comparable with those of naturally occurring HBV cores.

We thank Professor K. Murray and Biogen N.V. for providing E. coli extracts containing HBcAg, and Drs M. S. Pereira, A. M. Field and P. P. Mortimer and Professor K. Murray for helpful advice.

Tandem repeats in the N-terminal sequence of a proline-rich protein from corn endosperm

Asim Esen

Northern Regional Research Center, USDA/SEA/AR, Peoria, Illinois 61604, USA

Zeins, the prolamines of corn (Zea mays), are the most abundant storage protein fraction in corn endosperm. Like prolamines of other cereals, zeins are readily soluble in 60-70% alcohol solutions but are insoluble in aqueous buffer systems. The other major storage protein fraction in corn endosperm is glutelin, which is extractable with either dilute alkali or detergent. We have now extracted from corn endosperm a proline-

rich, zein-like protein fraction which we have purified by chromatography on phosphocellulose. Study of the N-terminal sequences of three chromatographic fractions for homologies shows that they are essentially identical. These N-terminal sequences include a hexapeptide Pro-Pro-Pro-Val-His-Leu, which is repeated in tandem at least six times, and probably eight times or more.

Moureaux and Landry1 and Paulis et al.2 independently discovered that some glutelin proteins were soluble in alcohol containing a disulphide reducing agent. This alcohol-soluble fraction of glutelin is referred to, amongst other names3-5 as alcohol-soluble reduced glutelin (ASG)6. Paulis and Wall7 showed that ASG could be separated into water-soluble and -insoluble fractions by dialysis against water. Water-insoluble ASG is similar to zein electrophoretically and in amino acid composition, whereas water-soluble ASG differs significantly. Water-soluble ASG constitutes ~5% of total protein in the corn endosperm (unpublished data).

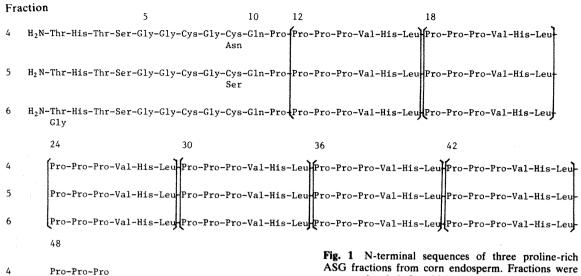

We recently⁸ fractionated ASG by chromatography on phosphocellulose and found that three late-eluting fractions, fractions 4 (peak 4), 5 (peak 5) and 6 (the late-eluting tail of peak 5), contained proteins similar to either the water-soluble ASG or the reduced-soluble (RS) protein described by Wilson et al.9. The amino acid compositions of these ASG fractions are essentially identical, but differ significantly from zein8. They contain a large number of proline residues (~26 per 100 residues) and are exceeded in proline content only by certain proteins in wheat omega-gliadin¹⁰, barley C-hordein¹¹ and human saliva¹². SDSpolyacrylamide gel electrophoresis showed that all three fractions are homogeneous and have a molecular weight (M_r) of 27,500. In contrast, they show extensive charge heterogeneity (14-16 components, with 5 predominant ones) on isoelectric focusing (IEF). All three IEF profiles are essentially similar, however, the differences being primarily quantitative.

N-terminal amono acid sequence analysis revealed that these proline-rich ASG fractions have identical sequences for at least 49 residues (Fig. 1). This degree of sequence homology suggests that the polypeptides are products of homologous genes which arose by duplication from an ancestral gene. Major heterogeneity was evident at only two positions (1 and 9). Glycine and threonine were found in an approximately equimolar ratio at residue 1 of fraction 6; at residue 9, in addition to cysteine, asparagine was detected in fraction 4 (Cys/Asn~1:1) and serine in fraction 5 (Cys/Ser ~1:2). The presence of serine and cysteine at the same position can be accounted for by a point mutation involving a single nucleotide substitution. In addition to positions 1 and 9, slight microheterogeneity was occasionally noted in the first nine positions, amounting to no more than 5-10% of the major determined residue. This may explain the heterogeneity of these fractions observed after IEF. There was no sequence heterogeneity apparent from residues 10-49, indicating possible evolutionary pressure for conservation of this sequence.

The N-terminal sequence of proline-rich ASG fractions 4-6 is extremely hydrophobic: 69% of the amino acids identified in the first 58 positions are proline, valine and leucine. In fact, proline accounts for 43% of the first 58 residues. On the basis of amino acid composition and estimated molecular weight8, it is expected that fractions 4-6 contain ~60 prolines out of a total of 225-230 residues, and the occurrence of 25 prolines in the first 58 positions indicates an uneven distribution of this amino acid. This is also true for histidine, where 9 (of 12-14 total expected) histidine residues occur in the first quarter of the molecule, making its N-terminus positively charged. Indeed, the occurrence of regularly spaced histidines in a region rich in proline. valine and leucine may be responsible for the solubility of fractions 4-6 in water, as charge repulsion between histidines could diminish hydrophobic interactions among nonpolar residues.

The most surprising observation from the data in Fig. 1 is that a hexapeptide, Pro-Pro-Pro-Val-His-Leu, is tandemly repeated at least six times, and probably a minimum of eight times, in

6

fractions 4-6, starting at position 12. This is the first report of so many identical tandem repeats of such long unit length occurring in a plant protein. There is some evidence that Tripsacum aestivum and Tripsacum monococcum gliadins and barley C-hordein, which are proline-rich, contain repeating pentapeptide sequences (D. D. Kasarda, personal communication).

Pro-Pro-

54

Pro-Pro-Pro-Val-His- X -Pro-Pro-Pro-Val-His-

Periodicity in amino acid sequences of some animal proteins (for example, collagen, keratin, silk fibroin, protamine and tropoelastin) has long been known 13-15. Identical tandem repeats, however, have been found in only a few proteins, most notably in freezng point-depressing glycoproteins 16 and tropoelastin 15,17. In tropoelastin, 4-, 5- and 6-residue-long units were found to be repeated in tandem in different peptides. Nontandem identical repeats have also been reported in proteins isolated from human saliva12,18

To determine whether the repeating hexapeptide Pro-Pro-Pro-Val-His-Leu from fractions 4-6 shows any sequence similarity to other proteins of plant or animal origin, the National Biomedical Research Foundation undertook a computer search for this repeating unit in all proteins for which sequence data were available, from mid-1980. Of 164,931 6-residue-long sequences from 1,439 proteins, none was identical to the repeating unit found in ASG fractions 4-6.

The presence of essentially a single N-terminal sequence in proline-rich ASG fractions was rather surprising in view of the extensive charge heterogeneity detectable by IEF in these fractions. Furthermore, it is widely believed that seed storage proteins are relatively free from selective pressures and thus can readily tolerate and accumulate random amino acid substitutions¹⁹⁻²¹. It is also surprising that 6-residue-long tandem repeats have identical sequences, with little indication of divergence of any repeating units. The invariance of this repeating sequence may be due to the following. Proline-rich proteins may have an important, presently undefined, biological function that places constraints on variations in their primary structures. This may not be tenable, however, in view of the fact that some inbred maize strains (for example, W64A) lack proline-rich ASG proteins and have no detectable abnormalities. Alternatively, duplication and divergence of the homologous prolinerich ASG genes from their ancestral gene may have occurred recently. This is the more plausible explanation as archaeological and palaeontological data suggest that corn was domesticated only 5,000-10,000 years ago, and that a wild corn existed

converted to their S-pyridylethyl derivatives and subjected to automated Edman degradations on a Beckman 890C sequencer, using 1M Quadrol programs 122,974 and 111,978 (ref. 21). The resulting phenylthiohydantoin amino acids were identified by HPLC and two-dimensional TLC.

as long as 80,000 years ago²². DNA hybridization data, however, suggest that early corn or its immediate wild ancestor may have diverged from its nearest possible progenitor, teosinte, 10-20 million years ago, and from its other possible progenitor, Tripsacum, 40 million years ago²³.

Obviously, tandem 6-residue repeats in proline-rich ASG fractions are colinear to 18-nucleotide-long DNA repeats. These DNA repeats may have arisen either by saltatory replication²⁴, by unequal crossing-over²⁵, or by one of the other mechanisms reviewed elsewhere²⁶. In fact, we postulate that repeats in proline-rich ASG represent an insertion into an ancestral prolamine gene from one of the repetitive sequence families of the maize genome, rather than from intracistronic tandem duplications involving an 18-nucleotide sequence. The isolation of mRNAS encoding proline-rich ASG polypeptides, the production of cDNA probes from these mRNAs, and hybridization of the probes with various components of maize DNA may elucidate the origin of these repeated sequences.

Activation of transcription of a yeast gene in *E. coli* by an IS5 element

Richard Jund & Gérard Loison

Laboratoire de Génétique Physiologique, IBMC du CNRS 15 rue R. Descartes, 67084 Strasbourg Cedex, France

pRG4 and pRG5 are two plasmids derived from pBR322 which carry an integrated yeast DNA segment (2.5 kilobases) containing the *URA1* gene^{2,3} and differ only in the orientation of the insert. Escherichia coli pyrD cells transformed by pRG4 recover the ability to grow on minimal medium whereas pRG5transformed pyrD cells do not3. The spontaneous integration of an insertion (IS) element into the cloned DNA segment corrects the absence of complementation in pRG5-transformed pyrD cells3. The new plasmid resulting from such an insertion event has been named pRG7 (Fig. 1). To determine the level at which the IS element affected URA1 expression, we assayed the RNAs which hybridized to each strand of URA1 DNA in various transformed pyrD strains, using as a probe single-stranded URA1 DNA cloned in phage fd106⁴. The results showed that the switching on of yeast gene by the IS element occurred at the transcriptional level, strongly suggesting that this IS element can serve as a mobile promoter in E. coli. The IS element has been identified as an IS5.

To determine which strand served as a template for the transcription of *URA1*, we cloned the 2.5-kilobase (kb) fragment containing *URA1* into the *Hin*dIII site of the replicative form of phage fd106^{4.5}. Phages carrying the yeast DNA in both directions were obtained from infected KB35F⁺ cells⁴. DNA from each type of phage was used to assay the *URA1* mRNAs in the two isogeneic yeast strains FL100 and *ppr1*-1⁶, a strain

Table 1 Transcription of the URA1 region in yeast

Yeast strain		Amount of RNA hybridized to the plus strand of URA1 DNA	Amount of RNA hybridized to the minus strand of URA1 DNA	
Expt 1 Expt 2	Wild-type FL100 ppr1-1 Wild-type FL100 ppr1-1	$ \begin{array}{c} 1.2 \times 10^{-5} \\ 6.8 \times 10^{-5} \\ 3.3 \times 10^{-5} \\ 15.3 \times 10^{-5} \end{array} $	$0.3 \times 10^{-5} \\ 0.4 \times 10^{-5} \\ 0.5 \times 10^{-5} \\ 0.9 \times 10^{-5}$	

Yeast cells were grown in minimal medium (Difco yeast nitrogen base 6.7 g Γ^{-1} , 2% glucose) at 30 °C. Cells were labelled in exponential phase using ³H-adenine (20 μ Ci m Γ^{-1}) of specific activity 17 Ci mmol $^{-1}$. Yeast RNAs were extracted from 10-ml cultures ^{15.16}. Conditions for hybridization of RNA to DNA fixed on nitrocellulose filters (Sartorius) are described in ref. 16. The nitrocellulose filters carrying probe DNA were prepared according to ref. 17. Specific hybridization of the cloned yeast DNA was measured in triplicate as follows: labelled RNA was incubated in a small glass vial with one filter loaded with 1 μ g fd-ural plus strand DNA and one filter loaded with 1 μ g of fd106 DNA. The strand which hybridized the most RNA was arbitrarily named the plus strand. To evaluate hybridization to each strand of the yeast DNA, c.p.m. retained on a fd DNA filter were subtracted from c.p.m. on a fd-ural DNA filter. The amount of hybridization was expressed as the fraction of radioactivity specifically retained versus the input. Conditions were such that the input of radioactivity per unit cell mass was the same for both strains. Expts 1 and 2 are two completely independent experiments.

constitutive for synthesis of dihydroorotate dehydrogenase. The regulatory mutation ppr1-1 affects transcription of the unlinked gene URA1, the level of URA1 mRNA being about five times higher in the ppr1-1 strain than that in the wild-type strain². The results presented in Table 1 indicated that in the wild-type strain yeast RNA hybridized to both strands of the cloned yeast DNA. About 83% of these hybridized RNAs were complementary to one strand, arbitrarily named plus, 17% to the other strand named minus. In the ppr1-1 strain, the level of the RNA hybridizing to the plus strand was about five times higher than that found in the wild-type strain, whereas the amount of RNA hybridizing to the other remained almost unchanged, showing that the plus strand carried the sequence complementary to URA1 mRNA. Hybridization to both strands of the 2.5-kb cloned DNA was still observed after subsequent purifications of the plus phage and thus could not be attributed to contamination of the plus strand by the minus strand. Rather, this suggested that the cloned fragment not only encompassed the entire URA1 sequence but additionally contained the end of a second

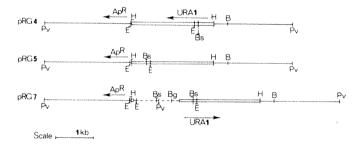

Fig. 1 Structure of plasmids pRG4, pRG5 and pRG7. The construction of these plasmids is described in refs 2 and 3. The DNAs are represented linearized after single cleavage at the PvuII site of pBR322¹. pBR322 DNA sequences are represented by a continuous single line, yeast DNA sequences by an open box and the IS element DNA by a broken single line. The sites shown for restriction endonucleases cleavage are as follows: E, EcoRI; H, HindII; B, BamHI; Bs, BstEII; Bg, BgIII; Pv, PvuII. The arrows indicate the direction of transcription of the ampicillin-resistance (Ap^R) gene¹ and of the URA1 gene. kb, Kilobase.

gene in the opposite strand. The orientation of the *URA1* region in each type of phage was determined by *EcoRI* restriction analysis of the corresponding replicative forms (not shown). The polarity of the virus strand being known⁴ and the template strand for *URA1* transcription determined to be the plus strand, the direction of transcription of *URA1* could be deduced to proceed from the internal *EcoRI* site towards the distal *HindIII* site (see Fig. 1).

We then assayed the RNAs which hybridized to each separated strand of the cloned yeast DNA in the E. coli pyrD strains transformed by pRG4, pRG5 or pRG7 (Table 2). In the pRG5-transformed pyrD strain, no dihydroorotate dehydrogenase activity was found, in agreement with our previous results3; no hybridization of RNA to the plus strand could be detected in typical pulse-label experiments, indicating that transcription of URA1 did not occur in this strain. One could propose two explanations for this absence of transcription. The first would be that there is a signal somewhere in the 5' end of the cloned gene that is recognized as a stop by the E. coli RNA polymerase and therefore impedes the transcription of URA1, an hypothesis which can be discarded because URA1 is transcribed when cloned in the opposite direction. The second explanation would be that no yeast sequence in this cloned segment is recognized as a promoter by the E. coli RNA polymerase; the transcription of URA1 would therefore depend on the existence of a pBR322 promoter and would only

occur by a readthrough mechanism. In support of this hypothesis, Stüber and Bujard have found that the ampicillinresistance gene of pBR322 could be transcribed from two promoters, one of which is located near the HindIII site and can serve to initiate the transcription of DNA segments inserted into this site. Notably, the direction of transcription of URA1 in pRG4 coincides with that of the ampicillin-resistance operon. No pBR322 promoter can be used to transcribe URA1 in pRG5, as the promoter of the tetracycline-resistance operon is inactivated by HindIII cleavage7. However, when URA1 is integrated into the BamHI site, which is located inside the structural gene for tetracycline resistance, again only one orientation of the cloned fragment allows expression of the URA1 gene3. In this case, the direction of transcription of URA1 coincides with that of the tetracycline-resistance operon. These results strongly support the hypothesis that URA1 requires a bacterial promoter for its expression in E. coli. However, it is surprising that the minus strand in the pRG5-transformed strain is very poorly expressed compared with the plus strand in the pRG4-transformed strain, although involvement of the same pBR322 promoter in both cases is suspected. This might imply that the minus strand contains sequences which signal inhibition of transcription in E. coli.

The interesting point is that in the pRG7-transformed strain, the transcription of URA1 is restored. This indicates that the integration of the IS element provides the promoter activity required by URA1 for its transcription in E. coli. A restriction map of this IS element shows that EcoRI, BglII, PvuII and BstEII cleave within the insertion, whereas BamHI and HindIII do not. According to this map, the size of the IS element is

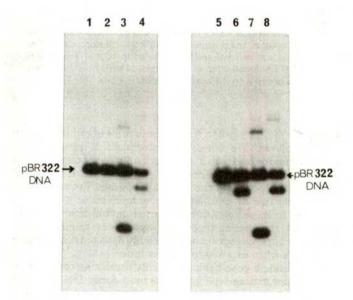

Fig. 2 Hybridization of the IS element controlling the expression of URA1 to IS5. pDI14 is a pBR322 plasmid carrying a 3-kilobase insert of Haemophilus haemolyticus DNA at the PstI site. pDI40 only differs from pDI14 in having an IS5 element integrated inside the *H. haemolyticus* DNA segment. The structures of these plasmids are described in ref. 9. The DNAs run on 0.8% agarose gels were as follows: lanes 1 and 5, ~4 ng of HindIII-digested pRG5 DNA; lanes 2 and 6, ~4 ng of HindIII-digested pRG7 DNA; lanes 3 and 7, ~4 ng of PstI-digested pDI14 DNA; lanes 4 and 8, ~4 ng of PstI-digested pDI40 DNA. After electrophoresis, the DNAs were transferred to a nitrocellulose filter¹⁰. Native pDI14 and pDI40 DNAs were made radioactive by 'nick-translation' (specific activity of each DNA was ~107 c.p.m. µg lated pDI14 DNA was hybridized to the transferred DNAs of lanes 1-4 and nick-translated pDI40 DNA was hybridized to the transferred DNAs of lanes 5-8. The HindIII insert of pRG5 DNA hybridizes neither to pDI14 DNA nor to pDI40 DNAs; the HindIII insert of pRG7 DNA does not hybridize to pDI14 DNA but does hybridize to pDI40 DNA.

Table 2 Expression of the URA1 region in E. coli pyrD strains transformed by various plasmids

Strain	Plasmid	Dihydroorotate dehydrogenase activity	Amount of RNA hybridized to the plus strand of URA1 DNA*		
E. coli pyrD	pRG4 pRG5 pRG7	7.2 <0.01 7.5	200×10^{-5} $< 10^{-5}$ 217×10^{-5}	2.7×10^{-5} 2.2×10^{-5} 2.3×10^{-5}	

E. coli pyrD cells were grown at 37 °C in minimal medium containing ampicillin (50 μ g ml⁻¹) and uracil (20 μ g ml⁻¹). The dihydroorotate dehydrogenase activity was assayed as previously described using an acellular extract from a 100-ml culture of exponentially growing cells. The activity is expressed in nmol of substrate transformed per min per mg protein.

A 10-ml culture of exponentially growing cells was labelled for 2 min with ³H-adenine (10 μCi ml⁻¹) of specific activity 17 Ci mmol⁻¹ Crude E. coli extracts were obtained by sonication. Conditions for hybridization were the same as in Table 1. The amount of hybridization was expressed as the fraction of radioactivity specifically retained versus the input.

actually ~1.2 kb and not 0.9 kb as previously estimated3. Our IS element has been shown to hybridize to IS5 (1,195 base pairs)8. using the Southern procedure 10 (Fig. 2).

Until now, only IS2 elements, and in one case reported recently11 an IS3 element, have been observed to activate bacterial gene expression in E. coli (see ref. 12 for a review). IS1 and IS5 elements were also found to activate the cryptic bgl operon in E. coli K-12, but in this case the IS elements served to disrupt an operator site rather than provide a promoter sequence13. IS2 was also shown to increase the expression of a cloned yeast gene (TRP5) in E. coli14. This is the first time that an IS5 element has been reported to exert a transcriptional effect on the expression of a cloned yeast gene.

It is not clear whether a sequence carried by this IS5 element is in itself sufficient to bestow promoter activity. For instance, some region(s) of the IS5 element might function as part of a promoter which would also involve yeast or/and even additional upstream pBR322 sequences. Such a possibility has already been discussed by Glandsdorff et al.11 in the case of IS2dependent gene activation.

This work was carried out in Professor F. Lacroute's laboratory, and we thank him for his interest in our work. We also thank Drs P. Starlinger and B. Schoner for sending us various cloned IS element DNAs, and Dr J. C. Hubert and Mrs Nguyen-Juilleret for help in some experiments. G.L. was supported by a Rhône-Poulenc fellowship.

Molecular rearrangement of mating-type genes in fission yeast

David Beach & Paul Nurse

School of Biological Sciences, University of Sussex, Brighton, Sussex BN1 9QG, UK

Richard Egel

Universitetets Genetiske Institut, DK-1353 København-K, Denmark

In the wild-type homothallic strain (h^{90}) of the fission yeast Schizosaccharomyces pombe, the mating type of a cell changes at almost every cell division1. Genetic analysis has suggested that mating-type switching results from copy transposition of genes from one of two storage cassettes into an active site2. This model is functionally similar to that already established for Saccharomyces cerevisiae3 but is different in that the three matingtype genes involved are tightly linked in S. pombe. Heterothallic strains in which mating-type switching is much reduced or absent arise from the homothallic wild type either through the irreversible loss of one of the silent storage cassettes (generating heterothallic stable minus strain h^{-s}) or through a genetic change which has been formally interpreted as a change in the switching signal at the mating-type locus (generating heterothallic normal plus (h^{+N}) and unstable minus (h^{-U}) strains. We have now isolated one of the mating-type genes mat-P, and have used it as a hybridization probe for sequence changes at the mating-type locus. We confirm that the genetic loss suggested for h^{-s} is due to deletion and demonstrate that the impairment of switching in h^{+N} and h^{-U} is correlated with a duplication.

The genetics of the mating-type locus are summarized in Fig. 1. To test this model at the molecular level, we have used the newly developed techniques for genetic transformation of S. pombe⁴ to isolate a functional copy of the mat-P gene from a

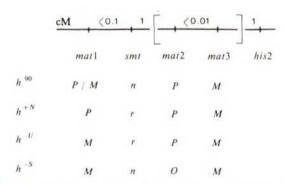

Fig. 1 Genetic map of chromosome II in the vicinity of the mating-type locus and the allocation of mating-type alleles to homothallic (h^{90}) and heterothallic h^{+N} , h^{-U} and h^{-S} strains of $S.\ pombe^{5}$. The momentary allele present at mat1, P (plus) or M (minus), determines the cellular mating type and has been derived by transposition from one of the two silent storage genes, mat2-P or mat3-M during the previous event of mating-type switching. The normal switching signal smt-n (a cis-acting sequence) of the homothallic strain h^{90} can change to smt-r, which reduces switching frequencies from $>10^{-1}$ to 10^{-4} or lower, giving rise to the slowly interconverting heterothallic strains h^{+N} and h^{-U} . The other heterothallic strain h^{-S} is presumed to be completely stable because it has lost the silent P information stored in mat2 (its switching signal is still normal and can be recovered by recombination). The mat3 gene was referred to as 'matX' in ref. 2. It has since been mapped to the vicinity of mat2 (R.E., unpublished results), but the relative order of mat2 and mat3 has not yet been determined.

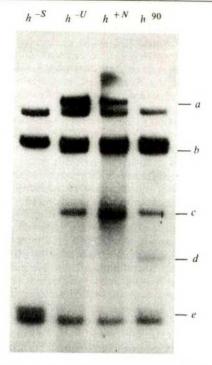

Fig. 2 Autoradiograph of 32 P-labelled pMT3.2 (nick-translated) hybridized to a Southern transfer of EcoRI-digested DNA of four mating-type strains, h^{-S} , h^{-U} , h^{+N} and h^{90} . All four strains are essentially isogeneic. $972 \ h^{-S}$ and $975 \ h^{+N}$ were obtained originally from Urs Leupold, and h^{-U} and h^{90} were isolated as spontaneous derivatives from h^{+N} before this experiment. DNA was prepared by lysis of protoplasts in 50 mM Tris pH7.6, 50 mM EDTA, 2% SDS at 65°C. The lysate was extracted with phenol, then chloroform, and precipitated with 0.5 vol of isopropanol. The precipitate was pelleted and resuspended in 10 mM Tris pH7.6, 1 mM EDTA. Small samples were digested with EcoRI and electrophoresed on 0.8% agarose gel at 2 V cm $^{-1}$ for 18 h.

gene bank of $S.\ pombe$ DNA. The strategy for isolating this gene was as follows. We constructed a diploid $S.\ pombe$ strain homozygous for $leu\,1^-\ his\,2^-\ h^{-S}$; such a strain contains only the mat-M gene and is therefore unable to sporulate. If the mat-P gene is introduced into the cell via a plasmid, the cell should become capable of sporulation once deprived of a source of nitrogen. In these conditions a normal diploid that is heterozygous at the mating-type locus sporulates spontaneously. Colonies containing spores can be readily detected because they stain black when exposed to iodine vapour.

To generate a gene bank potentially containing copies of all the different mating-type genes, we used donor DNA derived from the three mating-type strains h^{90} , h^{+N} and h^{-S} . These DNAs were mixed, partially digested with Sau3A and ligated to the unique BamH1 site in the tetracycline-resistance gene of the hybrid yeast/bacterial cloning vector pDB248 (ref. 4). pDB248 consists of the bacterial vector pBR322, the S. cerevisiae leu2+ gene which allows selection in leu1.32 strains of S. pombe and part of the 2 µm plasmid carrying the replication origin. A bank of recombinant molecules was generated in Escherichia coli and used to transform the diploid S. pombe strain, homozygous for leu1 his2 h-s. Transformants were selected as leu+ prototrophs on sorbitol-containing plates lacking leucine, at a frequency of ~1 in 2,000 viable protoplasts and 20,000 per µg of plasmid DNA. On exposure of the colonies to iodine vapour, 34 of the 70,000-80,000 transformants reacted with iodine and were found to contain spores and asci. The plasmids producing sporulating transformants were candidates for carrying an insert of mat-P sequences.

Three transformants were further analysed and found to be unstable. leu1+ and mat-P were lost from ~20% of the cells

even when clones were grown under leucine selection and both genes were almost always lost together, indicating that mat-P is linked to leu1+ on the unstable autonomously replicating cloning vector. Spores derived from the mat-P transformants were germinated and 48% of the resultant colonies were found to be leu1+ and iodine positive, although the extent of staining was variable. Some clones were found to be stable for both leu 1 and mat-P presumably as a consequence of integration into the chromosome. To determine whether this occurs at the matingtype locus, several haploids were crossed to a leu1 h+Nhis2 strain for tetrad analysis. Only one cross-over between leu 1 and his 2 was observed in a total of 81 tetrads with 4 germinating spores. As leu1 is normally 20 centimorgans (cM) from his2, their close linkage of <1 cM indicates that the plasmids have integrated at the mating-type locus adjacent to his 2. Furthermore, the h^{-S} haploid containing the integrated copy of the plasmid was found to have regained the mating-type switching properties of the h^{90} strain. This suggests that integration may have occurred at mat2, the silent store of mat-P information, as integration at mat1 would presumably result in immediate loss of mat-P during subsequent switching.

One of the mat-P plasmids was recovered from a yeast clone in which integration had not occurred, by re-transformation of E. coli (D.B., M. Piper & P.N., unpublished results). This plasmid, pMT3.2, was able to confer sporulating ability on diploid and haploid h^{-S} and on haploid h^{-U} strains, but not on h^{+N} . It therefore carries a functional copy of mat-P but not mat-M. The plasmid pMT3.2 was digested with EcoRI and the lengths of the fragments generated were measured. The insert into the BamHI site of the vector was found to be ~ 10 kilobases (kb) and to contain one EcoRI site. As the cloning vector pDB248 has no detectable sequence homology with the S. pombe genome, pMT3.2 can be used directly as a hybridization probe to analyse the chromosomal organization of the mating-type locus. DNA from the four mating-type strains h^{-s} , h^{-U} , h^{+N} and h^{90} was digested with EcoRI and hybridized with nick-translated pMT3.2 using the Southern procedure (Fig. 2). The most striking features of the hybridization pattern are as follows. Although the S. pombe insert in pMT3.2 contains only one EcoRI site, the probe hybridizes to six bands in the h strain, and thus some of the insert sequences must be present in more than one copy within the genome. Compared with h^{90} , the lacks three bands b, c and d (Fig. 2) at 5.4, 4.0 and 3.0 kb, respectively, while one small new band (Fig. 2, 1.7 kb) is apparent. On the other hand, in both h^{+N} and h^{-U} there is a prominent extra band (a, 7.2 kb) and loss of one weakly hybridizing band (d, 3.0 kb) compared with h^s

The simplest interpretation of these data is that h^{-s} arose from h^{90} by loss of the silent mat-P cassette, thereby generating a strain which never reverts to h^{90} and lacks certain restriction fragments. The bands which h^{-S} and h^{90} have in common may reflect sequence homology between the mat-P and mat-M genes, but some hybridization may be due to sequences adjacent to the mat-P gene which are not directly involved in mating-type determination. h^{+N} and h^{-U} carry a duplication of mating-type information. This may have occurred in two different ways: it could result from either a faulty transposition event in which the resident gene at mat1 was not excised during insertion of a new gene from the silent store, or unequal crossing-over between sister chromatids at the mating-type locus. If a copy of mat-P at the mat1 site recombined with the same gene at mat2 on the sister chromatid, the products would be a cell which had a duplication of mat-P and the other a deletion of mat-P. This model predicts that the arisal of h^{+N} and h^{-S} from h^{90} is a reciprocal event.

The duplication in h^{+N} and h^{-U} might be expected to reduce the rate of switching. When the duplication is removed there will be a reversion to h^{90} ; this occurs at a frequency of 5×10^{-4} . The Southern blot hybridization patterns do not distinguish between h^{+N} and h^{-U} although they presumably contain different mat 1 genes. This suggests that the region which differs between mat1-P and mat1-M is not cut by EcoRI and is of sufficiently

similar length as to generate bands that are indistinguishable on a gel.

Our results thus indicate the way in which heterothallic strains arise in S. pombe. They bear only indirectly on the mechanism of homothallic mating-type switching in this yeast but the isolation of the first hybridization probe for the mating-type locus opens the way for a more refined analysis of this process.

We thank Melanie Piper, Rachel McIntosh and Tove Friis for technical assistance, Sydney Shall for laboratory facilities, and Urs Leupold for helpful discussions. This work was supported by the CRC (D.B.), SERC (P.N.) and EMBO (R.E.).

The iron-oxygen bond in human oxyhaemoglobin

Boaz Shaanan

MRC Laboratory of Molecular Biology, Hills Road, Cambridge CB2 2QH, UK

Knowledge of the exact nature of the iron-oxygen bond in oxyhaemoglobin (oxyHb) is essential for the understanding of cooperative oxygen binding to haemoglobin (Hb)1. However, X-ray studies of oxyHb have previously been hindered by the tendency of oxyHb crystals to autoxidize. Here we report the stereochemistry of the haem-oxygen complex in human oxyHb, as determined by single-crystal X-ray analysis. Bent end-on geometry of the iron-oxygen bond in haem proteins, as predicted by Pauling², was first observed in the 'picket fence' complex³ and has since been observed in oxymyoglobin (oxyMb)4,5; in oxyerythrocruorin, however, the Fe-O-O bond is almost linear⁶. In oxyHb the Fe-O-O bond angle is 156°, intermediate between the 'picket fence' compound and erythrocruorin. The position of N^e of His E7 in the α -subunit suggests that it forms a hydrogen bond with the bound oxygen, as in oxyMb⁷. In the β -subunit, however, N° of His E7 is located further from the oxygen, suggesting that the hydrogen bond is weaker.

Crystals of human oxyHb were grown according to Perutz⁸, with minor modifications to retard autoxidation. Reflections to 2.1 Å resolution were recorded with an Arndt-Wonacott oscillation camera at -2 °C. After exposure, the crystals were dissolved and spectra obtained to determine the level of methaemoglobin (MetHb). None of the crystals used contained more than 10% MetHb. Details of crystallization, data collection and processing will be published elsewhere.

The human carbomonoxyhaemoglobin (HbCO) model¹⁰ served as a starting point for refinement, using the Jack-Levitt combined X-ray and energy method¹¹. At present, the agreement between observed and calculated structure factors, expressed as a conventional R factor, is 0.22. Positional standard deviations of atoms were estimated using a least-squares matrix⁵ and Luzzati plot¹².

Table 1 summarizes the stereochemistry of the haem-oxygen complexes in oxyHb, oxyMb and the 'picket fence' compounds. Figure 1 shows the striking difference between the Fe—O—O bond angles in oxyHb and oxyMb, that is, 156° (± 10) in both subunits of oxyHb compared with 115° (±5) in oxyMb⁵. This results from differences (0.5-1.5 Å) in the location of the distal residues (that is, His E7, Val E11 and Phe CD1) in contact with the ligand. Because of a change in position of the E helix and CD

Table 1 Geometry of haem-oxygen complexes in oxyHb, oxyMb and picket fence compounds

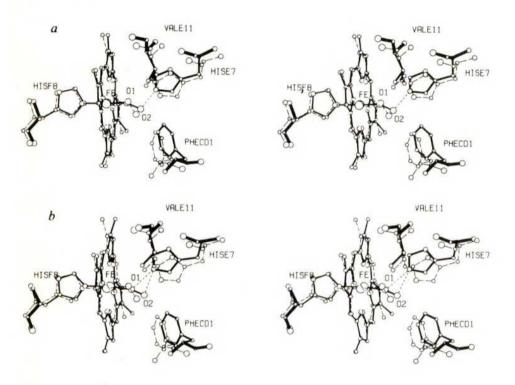

Fig. 1 Stereo view of superimposed haem environments oxyHb subunits and oxyMb. Haems were superimposed by least-squares fit and the other residues transformed accordingly. Thick lines denote oxyHb and broken lines, oxyMb. Note the upward movement of the terminal oxygen in oxyHb, following the distal residues. a, a-Subunit of oxyHb and oxyMb. Dotted line indicates a probable hydrogen bond, N^{ϵ} (His E7)—O2. b, β -Subunit of oxyHb and oxyMb: Nº is approximately equidistant from

O1 and O2 (dotted lines).

corner in oxyHb (see Fig. 1), these residues are further from the haem centre than in oxyMb. Thus, the haem pocket of oxyHb is more spacious than that of oxyMb. Extended Hückel calculations have shown that the iron-oxygen bond can vary between 120° and 160°, with only small consequent changes in energy (160° is, however, a favourable angle)^{13,14}. Hence, the more obtuse Fe-O-O bond angle observed in oxyHb may reflect either a reduction in steric constraints imposed upon the bound oxygen, or a different set of constraints.

Because of its loosely packed haem pocket, R-state Hb15 can accommodate CO, which binds to iron in a linear mode, more easily than Mb. In fact, the terminal oxygen in oxyHb (O2 in Fig. is close to the position occupied by the CO oxygen in HbCO. R-state Hb, therefore, has a higher O2/CO partition coefficient than Mb, which results in reduced O2/CO discrimination (the partition coefficient, $M = P_{1/2}O_2/P_{1/2}CO$, for *R*-state Hb is 200-250; that for Mb is 25-40)¹⁶.

Recently, Phillips and Schoenborn demonstrated by neutron diffraction that N" of His E7 forms a hydrogen bond with the terminal oxygen in oxyMb. In the α -subunit of oxyHb, N*—O2 is 2.7 Å and the geometry favours a similar hydrogen bond (Fig. 1a). In the β -subunit, N^{ϵ} of His E7 is approximately equidistant from O2 and O1 (3.4 Å and 3.2 Å, respectively; see Fig. 1b), the larger distance implying the presence of a weaker hydrogen bond with one or both oxygen atoms. Studies on the rate of formation of MetHb from oxyHb have shown that the α -subunit autoxidizes faster than the β -subunit^{17–18}. By forming a stronger hydrogen bond, the oxygen molecule in the α -subunit may become more polarized, thus allowing more rapid autoxidation.

The detailed structure of human oxyHb will be published elsewhere.

I thank Dr M. F. Perutz for suggesting the project and for continuing encouragement. I thank EMBO for a long-term fellowship.

BOOK REVIEWS

Physicist extraordinary

Rudolf Peierls

MARK Oliphant is one of the great personalities of the world of physics, whose career has had many very different facets. Original research in nuclear physics in the Cavendish Laboratory under, and in close collaboration with, Rutherford, was followed by leadership of the radar team at Birmingham which produced the cavity magnetron and by work with Lawrence at Berkeley on the electromagnetic isotope separation for the atom bomb. After the War came the idea of the synchrotron, conceived independently and probably before others, and the creation of a nuclear physics school at Birmingham, with the construction of a cyclotron and a proton synchrotron; then, after the return to Australia, a major share in the development of the National University and, after retirement from the laboratory, a term as Governor of his native state of South

But no list of this kind could bring out Oliphant's most characteristic quality, the fearlessness with which he speaks his mind, no matter whether his thoughts are popular or unpopular, never calculating their effect on his image. While therefore what he says and writes does not always please his listeners, they always respect his intrinsic honesty. This quality came out perhaps most strongly, and created the greatest surprise, in his last, most exalted position as Governor. The men chosen for such representative positions are often senior statesmen or military men, very conscious of protocol, and maybe stuffy. Stuffiness is a quality completely lacking in Oliphant, and his direct and outspoken ways went over well in a country where stuffiness is not welcomed.

He speaks with equal directness about his failures and errors of judgement, and this has made it easier for the authors to write this biography in his lifetime. Writing about living people who can answer back, can be embarrassing, but evidently not in this case.

The authors have interviewed Oliphant and members of his family, as well as many colleagues in his different spheres, and they have had access to many letters and other documents. As a result the book brings out Oliphant's personality vividly. Perhaps the best part of the book is the account of his ten years in Cambridge. The authors do not give much detail of his papers on nuclear physics, but then they are not writing for physicists. What comes out so well is the atmosphere in the Cavendish, and Rutherford comes completely alive. Oliphant was perhaps Rutherford's

Oliphant: The Life and Times of Sir Mark Oliphant. By Stewart Cockburn and David Ellyard. Pp.369. ISBN 0-9594164-0-4. (Axiom Books, Australia: 1981.) A\$19.95.

Oliphant in 1950, the year of his move from Birmingham to Canberra.

favourite pupil, and we understand why. The characters of these two men had much in common in their directness, and in their enthusiasm for the work. A lecture by Rutherford had made a deep impression on Oliphant when still a student, and had led to his resolve to get to Cambridge and work under Rutherford; the great respect and awe gradually gave way to genuine affection.

Yet he left Cambridge, as other collaborators of Rutherford had done, to branch out on his own in Birmingham. He took up his new post just before Rutherford's death in 1937. His intention was to build up nuclear physics in Birmingham, but the process was soon interrupted by the War. The book describes the radar work, and his abortive trip to Australia to offer his services to the Australian government when the radar problems at Birmingham had lost their urgency and the war in the Pacific was approaching his native country. Finding that no one was prepared to arrange for his services to be used, he returned to England, and soon afterwards joined E. O. Lawrence at Berkeley in work on the electromagnetic isotope separation for the atom bomb. Lawrence was another colleague to whom Oliphant had great affinity, and their relationship is also brought out very vividly here. The authors Colleges of Chence of Colleges of Chence of St. A P.C. describe the shock Oliphant felt when he heard of the use of the atom bomb on Japan, and his determination to work for solutions that would make future atomic war impossible or at least unlikely.

Back to academic life, to complete the construction of the cyclotron started before the War, and to start the proton synchrotron, based on an idea proposed by him but published by others first. The construction of two machines in a very confined space, and in a Britain beset by post-War shortages, using do-it-yourself methods as far as possible, was a typical Oliphant act of courage and optimism. The less ambitious of the machines, the cyclotron, gave little trouble; the proton synchrotron took much longer to complete than had been hoped for, and was ready only long after the similar, though somewhat larger, "cosmotron" at Brookhaven.

In fact the machine was completed only after Oliphant had left for his next assignment, the Australian National University at Canberra. The book describes the part he played in building up the spirit of the new institution, with all the struggle that involved, and also his choice of a machine for the physics department, a 10 GeV synchrotron powered by a homopolar generator. Looking back, this was clearly an error of judgement. He was again over-optimistic about the prospect and the time scale. If the machine had been completed as planned, it would have been by some years the first to reach this energy range, though even then the slow repetition rate would have made it difficult to use. As it is, only the homopolar generator was completed, but it will not drive a synchrotron and has instead found application in work on plasma physics. In spite of this disappointment, he succeeded in creating a physics department with many activities in different fields, and a staff of high quality.

Last, but not least, comes his term as Governor, which I have already mentioned. This again is described with warmth, though without glossing over some errors and embarrassments.

Taken as a whole, the book is perhaps a little longer than necessary. But it is a pleasure to read, and it does justice to a great character, whose integrity, frankness and directness set an example to us all.

Sir Rudolf Peierls was with Oliphant in Cambridge from 1935 to 1937, and in Birmingham from 1937 to Oliphant's departure for Australia. He moved to Oxford in 1963, where he is now Emeritus Wykeham Professor.

Membranes layer by layer

Clive Ellory

New Comprehensive Biochemistry, Vols I and II. Vol.I, Membrane Structure. Edited by J. B. Finean and R. H. Michell. Pp.271. ISBN 0-444-80304-1. (Elsevier/North-Holland Biomedical: 1981.) Dfl.140, \$59.50. Vol.II, Membrane Transport. Edited by S. L. Bonting and J. J. H. H. M. de Pont. Pp.362. ISBN 0-444-80307-6. (Elsevier/North-Holland Biomedical: 1981.) Dfl.140, \$59.50.

MEMBRANE expansion is a term that not only applies to certain important cellular processes, but also describes the status of the whole field of membrane biology. In addition, it seems to have become a clarion call to publishers. Predictably, however, books on the topic are extremely variable in quality, often representing unrefereed reportage at symposia. Happily, the present two works are excellent, comprising comprehensive and scholarly reviews by experts, each of whom describes the present state of knowledge in his area of membrane biology.

The depth in which subjects are covered in the first volume, Membrane Structure, is impressive, and is reflected by the relatively few (six) chapters of which it is composed. An initial contribution by the editors sets the scene and introduces the Singer-Nicholson fluid mosaic model - now ten years old and very much part of the established orthodoxy — as probably the last generalizable membrane model. They suggest new models will not be general, instead emphasizing the individuality of specific membranes at an advanced level of definition. Edidin produces a detailed and critical analysis of the results obtained from applying spectroscopic techniques to measuring molecular motions of membrane components, particularly the lateral diffusion of membrane proteins, op den Kamp reviews the evidence for asymmetry of both membrane proteins and lipids. Although agreeing that membrane proteins are always distributed in a completely asymmetric manner, he ends on a cautious note with regard to phospholipid asymmetry, counselling care in the interpretation of experimental results which rely on phospholipid modification during localization.

In his excellent review of membrane glycoproteins, Gahmberg starts by admitting that we do not know the reasons why all known cell surface proteins are glycoproteins. He finishes, however, on a more positive note by proposing two plausible roles for the carbohydrates attached to surface proteins.

The final two chapters deal with the demanding topics of membrane-bound enzymes (including the complexities of the adenyl cyclase system) and the structure and assembly of membrane proteins. Again the overall quality is impressive,

although some results are perhaps presented more optimistically than they deserve; for example, Freeman's discussion of Arrhenius plots could have included a word of caution on kinetic artefacts.

The credentials of the contributors to Vol.II, *Membrane Transport*, are equally impressive, but the topics are narrower or at least their treatment is less comprehensive. This is reflected numerically with 12 chapters instead of 6. Nevertheless, every contribution is worthwhile, and I particularly liked the review of anion-sensitive ATPase(s) by de Pont and Bonting, which raises the status of this system by focusing attention on the amount of information now available. In contrast, the contribution on SR Ca-ATPase seemed surprisingly lacking in data on structure and subunit composition.

The reviews on membrane permeability

for water and polar and lipophilic molecules by Sha'afi and Stein respectively, and the contribution by Weinstein et al. on the coupled transport of water reveal that we have made less progress towards understanding transport in membranes than we have towards elucidating their structure.

Stein's major contribution to Vol.II, on the kinetics of mediated transport, is presented with his usual rigour and vigour, and may have the consequence of promoting an uneasy conscience in those of us who publish papers defining membrane transport systems with less than the full kinetic treatment.

Technically the quality of printing and illustrations is good, and these are books which few membrane biologists can afford to be without. I hope this series can maintain its momentum and adhere to the overall title of the New *Comprehensive* Biochemistry.

Evolution: opinions, axioms and "isms"

Jonathan Howard

Evolution: Genesis and Revelations, with Readings from Empedocles to Wilson. By C. Leon Harris. Pp.339. Hbk ISBN 0-87395-486-6; pbk ISBN 0-87395-487-4. (State University of New York Press: 1981.) Hbk \$29.50, £20.65; pbk \$9.95, £7. Science, Ideology, and World View: Essays in the History of Evolutionary Ideas. By John C. Greene. Pp.202. Hbk ISBN 0-520-04217-4; pbk ISBN 0-520-04218-2. (University of California Press: 1981.) Hbk \$16.50, £11.50; pbk \$5.95, £4.

DESPITE a respectable suit of clothes, Darwinism remains deeply controversial. Even intricate internal disputes, over cladistics, over sociobiology, spill over into the public domain in extraordinary displays of bad temper in the popular press (if I may so designate, in this context, *The Times*). It is quite funny how many people feel entitled to express a public opinion regarding, say, the validity of the theory of evolution, from a standpoint of the most abysmal ignorance of any biological phenomena at all save the workings of their own bodies.

Controversy, if raucous enough, takes the reading public to the bookshops, only to be confronted with the mountain of Darwin and evolution studies. Nothing is more intellectually stultifying than to be faced with too much to read, yet more and more stuff is pressed on our attention. If, as seems likely, the evolution debate in the wide sense marks one of the most farreaching intellectual revolutions in history, it would be a pity to devote what little time

one has to reading the wrong books. If the publishers refuse to discriminate between worthwhile and trivial books, the critics must.

Here is such a discrimination. I have two review copies of books on the history of evolutionary ideas, one a flabby paperback by a (to me) unknown biologist, the other an elegant hardback by a distinguished historian of biology. But if the general reader based his judgement on these superficial observations, and settled for the elegant book by the distinguished author, he would make a grave mistake. For it is not worth his attention, while the less favoured volume is brilliant and original, and still more exceptional in being very funny. Evolution: Genesis and Revelations, with Readings from Empedocles to Wilson is the punning, bathetic title of C. Leon Harris's primer in the history of evolutionary ideas. Brief readings from the evolutionary masters are sandwiched between essays by Harris in which he first introduces, and later discusses, his readings for the session. The great joy of the book is that it is deeply opinionated. There is nothing more agreeable than finding a scholar with a clear point of view, clearly stated, and supported with a will and a wit. Harris has all of this. His discursive essays cover an extraordinary range, each one a gem of concentrated opinion and argument which flows onto the page at a terrific pace. Sometimes, indeed, the pace seems too great for the constraints imposed by English grammar, but after reading a few pages I could

forgive Harris even that. The first few chapters of Genesis (in a most bizarre translation; could it be a Gideon Bible?) provoke a savage attack on the intellectual folly of modern creationism:

The idea of equal time for alternative theories is seductive to fair-minded people, but if creation is not scientifically supported it has no more right to equal time than the stork theory of childbirth.

Excerpts from Augustine and Aquinas bring an essay on the power of prejudice constructed around McCarthyism and Close Encounters of the Third Kind. Readings from Diderot, Maupertuis and Lamarck are followed by an essay on visual illusion as a metaphor for scientific creativity. Having planted his idea, Harris is happy to point to its limitations:

... visual illusions, though interesting and perhaps useful as models of creativity, are not as emotionally satisfying as the real thing. No scientist who has lost sleep because of the thrill of creating his own theory will underestimate the power of inspiration. We must go to another model to study this emotional component of creativity. One such model for the creative scientist happens to be a chimpanzee named Sultan, who one day discovered that he could connect two sticks and rake a banana into his cage. He got so excited over his creativity that he forgot to eat the banana.

It would be wrong to leave the impression of Evolution: Genesis and Revelations as a collection of quick-fire one-liners. Harris is funny and original in his approach, but he is also extremely thoughtful nearly all the time. Unexpectedly, however, he makes extraordinarily heavy weather of his discussion of Darwinian evolution, following readings from Darwin and Wallace. It is here, if anywhere, that one might hope that so clear and refringent a mind would throw new light, or at least make a new joke. Well, we get the new joke, in the shape of "Harris's First Law of Knowledge: Belief in the truth of a theory is inversely proportional to the precision of the science", but no new light. Indeed I am prepared to match Harris's trenchant style and say that I think his claim of axiomatic status for Herbert Spencer's phrase "survival of the fittest" is misleading at best, and at worst, wrong. I cannot accept that a noun phrase can ever be an axiom. 'Survival of the fittest' is no more an axiom than "C. Leon Harris". Let us suppose that Harris intends "the fittest survive" every time he says "the survival of the fittest". Does this truism indeed lie at the root of Darwinism, and is it really necessary to assimilate it as an axiom to appreciate the quality of Darwin's thought? Certainly not. The phrase, and its axiomatic form, are sloppy portmanteaux. The foundations of Darwinism are generalizations from experience and lend themselves easily to falsification. They are acceptable because they have not yet been falsified. To put the generalizations simply, there is heritable variation between

individuals, and individual reproductive performance is not independent of individual variation in other characteristics. Not as catchy as "survival of the fittest", but at least nearly right.

If "survival of the fittest" can lead so acute a mind as C. Leon Harris's into folly, we should perhaps learn to avoid the coiner of the phrase, in case he should disguise any more complex truths as simple falsehoods. I propose that books on the history of evolutionary ideas are to be avoided in direct proportion to the number of references they make to Herbert Spencer. Using this criterion, we should certainly select Harris, with not a single reference. and A.O. Lovejoy's classic The Great Chain of Being. By the same lights we should unhesitatingly reject John C. Greene's Science, Ideology, and World View, the second of my two books. Greene devotes almost as much space to Spencer as to Darwin, even coining the unhappy term Spencerianism-Darwinism to encapsulate his sense of a zeitgeist. Spencer had a total inability to make himself clear. He also wrote at inordinate length. (Publishers were more responsible in the nineteenth century: one of the most important facts about Herbert Spencer is that he was obliged to publish the ten monstrous volumes of the Synthetic Philosophy at his own expense). It is no surprise, therefore, that the working of Herbert Spencer's thin ore had to wait until the mother lodes had been worked out. If C. Leon Harris lives in a world of bright lights and dark shadows, John C. Greene lives in a penumbra of obscure "isms" (a horrific word which actually introduces one of his essays). In a parody of scholarship, Greene includes part of some correspondence between himself and Ernst Mayr, concerning Greene's doomed attempt to confine the use of the word "Darwinism" to a package of threadbare Victorian prejudices. As Mayr rightly says,

You may make a few sociologists happy by inflicting that package of Spencerian concepts upon Darwin, but those who probably use the word Darwinism the most will simply ignore it.

Where I have the greatest sympathy for John C. Greene's book is at the end of his last essay where he appeals with a gentle candour on behalf of the moral imagination of man against the spiritless encroachments of prescriptive sociobiology. Harris, too, ends his book with prescriptive sociobiology, but with characteristic combativeness he uses a muddy piece of Wilsonian gobbledygook as an excuse for whipping "the Marxist opponents of biological determinism". This may be another elaborate C. Leon Harris joke, but it is subtly done and for once I cannot see even a hint of a smile.

Jonathan Howard is at the ARC Institute of Animal Physiology, Babraham, Cambridge, and author of Darwin, recently published by Oxford University Press.

Scattering wisdom

Roger Pynn

Pulsed Neutron Scattering. By C.G. Windsor. Pp.432. UK ISBN 0-85066-195-1; US ISBN 0-470-27131-0. (Taylor & Francis/Halsted: 1981.) £25, \$85.

A GENERATION ago, a mutually beneficial relationship between solid-state physicists and the growing community of reactor specialists resulted in the birth of neutron scattering. Subsequently this field has grown to attract scientists from many other disciplines; chemists, biologists, metallurgists and even archaeologists have profited from the ever-increasing sophistication of neutron spectrometers.

Now, as reactor-based facilities are nearing their maximum performance, a new symbiotic relationship is beginning as neutron scatterers take over unfunded particle accelerators to produce pulsed neutron sources. This book describes such sources and the spectrometers which will use them. Although the book will probably be used principally for reference, the writing is sufficiently fluent that it can be read from cover to cover without undue stress. Indeed, the reader who does so will be rewarded by the occasional throw-away line incorporating practical wisdom in a pleasantly unpretentious style. The author has avoided irrelevant detail and the explanations are generally easy to follow. This is in no small measure the result of an excellent use of figures to explain the physical conformation of assorted hardware, as a guide through reciprocal space and to present illustrative experimental data. Mathematics, too, has been used intelligently. Where a mathematical derivation will be instructive, it is provided; otherwise results are usually quoted with sufficient reference to original work to allow the enthusiastic reader to find the derivations if he should need them. The simple, but usually neglected, expedient of "putting the numbers in" is frequently used to good effect, leaving the reader with a feeling for quantities as disparate as energy-resolution and moderator size.

As well as being an excellent compendium of much currently accepted wisdom, the book contains a number of contributions which are new. For example, detailed comparison of the performance of reactor and pulsed-source spectrometers has not previously reached a wide audience. Although not uncontentious, Dr Windsor's contribution in this field will certainly quell much argument — a curious effect often observed when fact is injected into a debate. The book also provides a

Academic Press have issued a condensed edition of Daniel Hillel's twin volumes, Fundamentals... and Applications of Soil Physics (for review see Nature 295, 466, 1982). The new book, Introduction to Soil Physics, costs \$22.50, £14.50 in paperback.

basic practical guide indispensable to anyone attempting an experiment with a pulsed-neutron spectrometer; in fact the numerous general remarks about experimental technique and spectrometer design are equally useful for the reactor-based scientist and the book should be compulsory reading matter for any new graduate student in the field. It is refreshing to find a discussion of the health hazards associated with working in weak irradiating fields; one wonders why a subject of such enormous potential importance has escaped attention in previous treatises on neutron scattering.

Apart from trivial typographical errors, I can fault the book only on two minor scores. In my view the first chapter does not do justice to its title of "Beyond Thermal Neutrons". I was expecting to be told of new science to be studied but read only the standard liturgy on the usefulness of neutron scattering. The chapter is really a thumbnail sketch of classical problems in neutron scattering and should have been titled as such. My second, less serious, objection concerns the partial use of SI units (for lengths only apparently). This is insufficient to satisfy the pedant but is more than enough to be irksome to those schooled in the conventional usage.

Roger Pynn is a solid-state physicist at the Institut Laue-Langevin, Grenoble, and a consultant for the Los Alamos National Laboratory pulsed neutron project.

Relating to halogenated hydrocarbons

Alastair Hay

Halogenated Biphenyls, Terphenyls, Naphthalenes, Dibenzodioxins and Related Products. Topics in Environmental Health, Vol. 4. Edited by R.D. Kimbrough. Pp.406. ISBN 0-444-80253-3. (Elsevier/North-Holland Biomedical: 1981.) \$95, Dfl. 195.

TEN years ago the only environmental pollutant people were familiar with was DDT. Today you could list dozens of additional names. Two types of chemicals which would be included are the polychlorinated biphenyls (PCBs) and the polychlorinated dibenzodioxins (PCDDs).

Both the PCBs and the PCDDs, known collectively as chlorinated hydrocarbons, have been widely discussed, but the halogenated isomers of these compounds are not as well known. This new book on halogenated hydrocarbons will remedy this situation. Here, for the first time in a single volume, the properties of the PCBs and PCDDs are considered in relation to the whole family of halogenated hydrocarbons.

In the case of the PCBs there is some irony in the fact that the very physical properties which made these chemicals so popular are the reasons why they are so much of a problem today. The attributes of the PCBs were said to include thermal stability and resistance to both oxidation and chemical degradation. An estimated 1 million tons have been produced since 1930.

Numerous surveys have shown that the residues of PCBs can be detected in human beings. The problem appears to have been caused by eating food — and fish in particular — contaminated with PCBs, simply because there is such an abundance of these chemicals in the environment. Once these facts were known the bottom dropped out of the PCB market. Government regulations — long overdue — helped to hasten their demise. But it was only production which was affected; we still have the mess to clean up.

It is a different problem with the PCDDs, which are produced as unwanted by-products in the course of making chlorinated phenols. Often they remain as contaminants in the finished phenolic product, some of which are widely used. Pentachlorophenol, for example, is a common wood preservative. And 2,4,5-trichlorophenol — contaminated with the highly toxic 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD) — is the starting point for the manufacture of the herbicide 2,4,5-T.

Although the threat from environmental exposure to both PCBs and PCDDs is still unknown, there is much more evidence about the hazard to workers occupationally exposed to them. It emerges that, as far as toxicity is concerned, there are

many similarities between the two substances.

In her introduction to this book, Renate Kimbrough says that it was thought to be desirable to discuss PCBs, PCDDs and related compounds in one book to help convey "a better understanding of their action and the complexities of their toxic effects".

The book does just that and it does it very well. Kimbrough has persuaded leading scientists in the field to discuss the chemicals in depth and to draw comparisons between them wherever possible.

The subjects included cover everything from the chemistry of these chemicals to their production, usage, and animal and human toxicology. In addition, there are valuable case studies of human populations exposed to PCBs in Japan and to TCDD at Seveso in Italy. The last chapter, by the editor herself, discusses the problems and health effects of occupational exposure to such substances.

The book is likely to become one of the standard texts for both students and researchers concerned about the health effects of exposure to PCBs, dioxins and their ilk. It is a joy to read a book as well edited as this, where there is no overlap between chapters and where all the contributors have stuck to their brief. The reader is left in no doubt that the toxicity of these halogenated aromatic compounds is indeed complex, but that there are many similarities between such chemicals in the way they exert their toxic effects.

Alastair Hay is a Lecturer in the Department of Chemical Pathology at the University of Leeds.

Foram stratigraphy

F.T. Banner

Stratigraphical Atlas of Fossil Foraminifera. Edited by D.G. Jenkins and J.W. Murray. Pp.310. UK ISBN 0-85312-210-5; US ISBN 0-470-27191-4. (Ellis Horwood/Halsted: 1981.) £25, \$79.95.

IN ONE concise yet comprehensive handbook, the value of fossil foraminifera to the stratigraphical geology of the British Isles is demonstrated at last. Before this publication, the information was scattered and no clear over-view could readily be obtained. Now, a collaboration by 23 authors (drawn from the petroleum industry, industrial consultancies, universities and the Institute of Geological Sciences) has provided a summary of all useful, published information, and careful

editing has presented it systematically and intelligibly.

Each of the 12 chapters outlines the stratigraphical base for the micropalaeontology of each successive geological interval. The foraminiferal record of the Pre-Carboniferous is poor, but in succeeding strata the value of foraminifera to their biostratigraphy becomes very apparent. The seven stages which comprise the British Carboniferous succession may be recognized and divided on the distribution of foraminiferal genera alone. The following chapters on the Permian, Triassic, Jurassic, Cretaceous, Palaeogene, Neogene and Quaternary intervals demonstrate how the stages, macrofossil zones (where they exist) and principal lithostratigraphic units are characterized by foraminiferal genera or species and by their assemblages. One short chapter summarizes the available information on the North Sea Cenozoic

In all, 570 important foraminiferal taxa are illustrated (usually by scanning electron microscopy, but, where hard limestone lithofacies predominate, by optical thin sections), and for each the essential taxonomy and morphology are outlined and the source of the illustrated specimen is noted. Where it is possible to do so, stratigraphic ranges (as syntheses or as objectively recorded occurrences) are illustrated by graphs. Each chapter on stratigraphy also records the whereabouts of the more important reference collections. Where it can be attempted, there are discussions on palaeoenvironmental and palaeofacies influences stratigraphical record; the last short chapter outlines the successions of foraminiferal assemblages recognized through the whole Phanerozoic, as a product of both evolution and of changing environments.

This is a most useful book; it will become a standard reference for all stratigraphic geologists and micropalaeontologists concerned with the post-Devonian strata of the British Isles. The format is clear, convenient for reference and methodical; the printing of text, diagrams and photographs is to a high standard. Some users will argue with the nomenclature which has been employed, and others will fault the taxonomy, but this is inevitable. More serious criticisms are that the essentially provincial scope of the book is not indicated by its title, and, in some chapters more than others, the welter of local British place-names (not adequately clarified by location maps) will confuse the overseas reader. This said, the editors, authors, publishers and the British Micropalaeontological Society are to be congratulated on this concise, attractive and much-needed volume.

F.T. Banner is Professor in the Department of Oceanography at the University College of Swansea.

Rules for the environmental game

David Dickson

DDT: Scientists, Citizens and Public Policy. By Thomas R. Dunlap. Pp.318. ISBN 0-691-04680-8. (Princeton University Press: 1981.) \$24.50, £13.10. The Reserve Mining Controversy: Science, Technology, and Environmental Quality. By Robert V. Bartlett. Pp.293. ISBN 0-253-14556-2. (Indiana University Press: 1981.) \$17.50, £10.50.

"I've never seen a company, even among the most enlightened, that considered environmental affairs to be anything more than a public relations problem" one of the three members of President Carter's Council on Environmental Quality said shortly after returning to his previous role as an environmental activist earlier this year.

The charge is far from one-sided. In an important sense, the various environmental debates that have taken place in the United States over the past 20 years have, indeed, been part of a large public relations game. Refusing to believe that a serious problem exists, many private companies have been more concerned with demonstrating the legitimacy of their existing practices than with volunteering the need for stronger federal restrictions. For its own part, the environmental movement recognized at an early stage the need to operate in a highly-visible public arena. Close relations with the mass media, reinforced by a well-developed sense of what makes a good news story, helped generate a mostly-sympathetic press, which in its turn served to mobilize public support.

Behind the public relations front, of course, more serious issues have been fought out. The growth of the environmental movement in the early 1960s was one of the first significant challenges to traditional mechanisms for the control of both industrial technology and its sideeffects. Previously, discussion about the environmental impact of new industrial or agricultural practices was contained largely within professional circles of scientists and physicians. The public had little cause - or inclination - to question the views of those it accepted as experts. The environmental movement openly challenged this mould. What started as a few isolated protests soon snowballed, in the face of apparent official indifference, into a nation-wide bandwagon on which many politicians were quick to jump. In the process, channels for public participation were opened up that significantly increased the opportunities for non-professional groups to intervene in the process of determining what technical innovations were and were not socially desirable. The most important development was the National Environmental Protection Act of 1969. By permitting environmentalist

groups to question the scope and adequacy of "impact statements" required for any major federally-funded project, NEPA provided a platform from which challenges to a wide range of government initiatives could be launched.

Even before NEPA, however, the environmentalist movement had found that, if public relations was its most effective political weapon, the courts were its most advantageous battle-ground. The courts were relatively neutral territory where environmentalists could set their own agenda and argue on equal terms with government administrators and industrial manufacturers alike. No where were the benefits of this strategy more clearly demonstrated than in the campaign which eventually led to the decision of the Environmental Protection Agency to ban the use of DDT in 1972.

Production of DDT in the United States had risen to about three million pounds a month by the end of the War, and shortly afterwards it entered civilian use with a reputation of being such a miracle chemical that one entomologist speculated that it might eventually banish all insect-borne diseases from the Earth. Yet as its use to protect agricultural crops, promoted by government scientists, grew rapidly, the first reports of mortality among birds and fishes began to be heard from wildlife biologists, indicating that DDT might not be the complete miracle that it appeared.

The early reports were not ignored. But neither, as Thomas Dunlap demonstrates in his closely-researched history of the campaign against the pesticide, DDT: Scientists, Citizens and Public Policy, were they initially taken very seriously. To farmers and pesticide manufacturers, the death of a few robins was a small price to pay for the benefits that the pesticide had brought.

The turning-point came with the publication of Rachel Carson's Silent Spring in 1962. Mrs Carson presented the various data that biologists had collected showing the different effects on wildlife that DDT seemed to be having, in particular how it was being concentrated through the food chain. But she went further, using the raw data to build an indictment of modern industry that soon became a battle-cry for the environmentalist movement, turning many conservationists into political activists.

If it took only one individual to open up the issue, more effort was needed to secure political change. Much of Dunlap's book is taken up with a close description of the case against DDT that was presented in 1968 by the newly-formed Environmental Defense Fund against the state of Wisconsin. Selecting its legal ground carefully, the EDF was granted a legal hearing to evaluate its claim that the scientific

evidence against DDT, for instance its link with declining bird populations such as that of the peregrine falcon, was sufficient to have the chemical declared an environmental pollutant for the purposes of regulation.

The EDF won its case. A sympathetic judge agreed that the evidence against DDT was sufficiently damning, and that there was no identifiable level beneath which DDT could be claimed to be completely harmless, a conclusion which undoubtedly contributed to the EPA's decision to phase out the chemical in 1972. Yet as much as the verdict itself, it was the publicity generated by the court case that provided some of the most effective spinoff. For it helped to generate a wave of public support for strict environmental laws — such as NEPA — that sympathetic legislators were quick to pass through Congress.

Industry, too, learnt its lesson from the Wisconsin hearing. The National Agricultural Chemicals Association initially sent only one retired attorney, a former counsel for the Velsicol Chemical Corporation, to present its defence of DDT. Having little reason to doubt that the arguments about the lack of evidence of DDT's harmfulness, which had proved successful in previous government regulatory proceedings, would again prevail, he was unprepared for either the style or the strength of the environmentalists' carefully-prepared attack. Even if it was a public relations battle, the symbolism of the loss in Wisconsin had to be taken seriously — a message which the chemical industry gradually took to heart during the 1970s.

The path seen in the struggle against DDT, culminating in hearings before the Environmental Protection Agency in 1971 and its eventual ban by EPA administrator William D. Ruckelshaus, was soon to become familiar. A similar process led to the ultimately-successful efforts by residents of Wisconsin's neighbouring state, Minnesota, to stop the Reserve Mining Company from discharging waste tailings from its taconite mill directly into Lake Superior, the largest inland sea in the Western Hemisphere.

In The Reserve Mining Controversy: Science, Technology and Environmental Quality, Robert V. Bartlett describes how the final outcome of that campaign, fought in various state and federal courts over a period of more than ten years, was as much the result of changing public perceptions as a neutral assessment of scientific evidence that the tailings discharged into the lake were causing harm.

The parallels with the DDT campaign are close. Just as the first critics of DDT based their case on the environmental effects of the pesticide which much of public opinion could dismiss as relatively harmless, so the first complaints against Reserve Mining, which had been given permission to discharge its tailings into the

lake when building its plant in 1947, focused on the discoloration of the water that the discharge appeared to cause, even though there was no direct evidence that the discoloration was causing significant biological damage.

Similarly, just as the final nail in DDT's coffin was the discovery early in 1969 that the chemical was a potential human carcinogen, so the federal order requiring Reserve Mining to find a land-based depository for its tailings — the result of a drawn-out suit against the company filed by the Department of Justice at the instigation of the EPA — hinged on the close morphological similarity between particles in the taconite tailings and asbestos fibres which scientists were beginning to demonstrate posed a significant hazard to health.

Bartlett, like Dunlap, provides a useful account of the twists and turns of the legal proceedings. The Reserve Mining controversy provides, as he points out, perhaps one of the most dramatic examples of the difficulties facing courts that are asked to decide on relatively complex scientific issues with legal equipment often ill-suited to the task. Each side in the dispute exploited the ambiguity of evidence about the environmental and health effects of the taconite waste to its own advantage, applying criteria of "truth" and "legitimacy" entirely foreign to conventional scientific discourse. As Bartlett points out, the dilemmas faced by the courts on such issues are partly the result of built-in tendencies of the political system in the United States to try to resolve conflict through adversary litigation rather than consensus-based planning. Dunlap, however, goes further to argue that the environmental problems raised by persistent pesticides such as DDT are not merely the result of unthinking industrial growth, or shifting public perceptions, but have deeper social and political roots. Among these, he suggests, is a "technicalfix" mentality to pest control that was reinforced by the professional self-image of economic entomologists, physicians' concepts of health and disease, and the economic motivations of farmers and pesticide manufacturers.

The significance of this message is unlikely to disappear. The climate of public opinion has changed since the days when the environmentalist movement was at its height, yet the change may not be as dramatic as many in the Reagan administration would like to believe. Plans to overhaul the Clean Air Act, for example, offered as a pre-election promise to the auto industry in 1980, have been postponed largely on the grounds that the political price in terms of lost popular support would be too high. Rather than abandoning the ideal of environmental protection, the administration is seeking more subtly to change the ground-rules.

The lesson of both of these books is the need to treat semantics warily. In both the DDT and the Reserve Mining disputes, the struggle over the proper treatment of the natural environment became clothed, for legal purposes, in a scientific language that as often seemed to obscure as clarify the real nature of the conflict. The problem is not unique to the United States, but it tends to be exacerbated in a country where, as one social scientist recently put it, "the gap between political ideal and political reality is a continuing central phenomenon".

David Dickson was Washington News Editor for Nature from 1977 to 1982.

AI in chemistry

R. Venkataraghavan

Applications of Artificial Intelligence for Organic Chemistry: The Dendral Project. By Robert K. Lindsay et al. Pp.194. ISBN 0-07-037895-9. (McGraw-Hill: 1981.) \$39.50, £19.95.

Applications of Artificial Intelligence for Organic Chemistry provides an excellent overview of a discipline that is playing an increasingly important role in problemsolving techniques using computers. The volume takes the reader through the definition of a problem in organic chemistry, concepts of advanced computer techniques, applications and, finally, to some interesting observations and conclusions of the authors. The applications cited in the book represent the research carried out by a team of interdisciplinary scientists, and provide some unusual and thoughtprovoking perspectives on the promise of computing in this area.

Emphasis is placed on the utilization of spectrochemical data and Dendritic Algorithms for structure-elucidation problems. The evolution of the Dendral project and its current capabilities clearly show the potential of computer-based techniques in the symbolic manipulation of complex information. The application of these techniques, however, is not confined to organic chemistry; in time they will undoubtedly be used to tackle a number of other problems in applied science. Certainly, the discussions of design considerations and the choice of computer-based tools should benefit those readers involved in the development of a variety of complex software projects.

This concise volume, representing the fruits of several years of active research, will prove to be a valuable source book for all seriously interested in the applications of computer techniques to problems in organic chemistry. It is to be hoped, too, that its influence will spread to associated disciplines and beyond.

R. Venkataraghavan is the Manager of the Research Applications Development Department at Lederle Laboratories, Pearl River, New York.

nature

22 April 1982

Zeal on secrecy could backfire

Admiral Bobby Imman of the CIA knows the danger that his crusade to alert US researchers to Soviet espionage could make academics abreact. But what else is the Administration looking for?

The Reagan Administration may be heading for a confrontation with US universities reminiscent of the Vietnam era. The issue is the tradeoff between national security and academic freedom in the research universities and the charge by Administration officials that, if something is not done, US campuses will become the targets of intensified Soviet intelligence efforts to gain advanced knowledge in genetic engineering, very high speed integrated circuits, lasers and the like. So far, the dialogue between the Administration and several spokesmen for university science has been restrained, even cordial. But there is already some hardening of positions on both sides, and some Administration ire that the scientists are not cooperating, as well as some campus resentment of the calls for self-policing.

Some of this resentment surfaced on 29 March when two subcommittees of the House Science and Technology Committee of the
US Congress held a joint hearing to gather the Administration's view of
how the free flow of research threatens national security. The star
witness was Admiral Bobby R. Inman, the deputy director of the
Central Intelligence Agency (CIA). Inman was formerly director of the
National Security Agency (NSA), the government's secret code
agency, where he provoked a dialogue with university mathematicians
on the dangers of publishing advances in cryptography — and even got
some to submit papers voluntarily for government censorship. In
January of this year, Inman caused a stir when he ventured to the
annual meeting of the American Association for the Advancement of
Science and suggested that unless scientists themselves devised
mechanisms to prevent leaks to the Soviet Union, the government
might require them to submit their research to censorship before
publication.

At the House hearing in March, Inman elaborated his view of Soviet technical espionage in the United States, US counter-espionage and the campuses. At present, he said, approximately 70 per cent of Soviet technical intelligence comes through purchases of hardware - some legal, some illegal. Moreover, the Soviet Union does "a very thorough vacuum cleaning of anything in the public sector". Finally, there is a smaller effort, which has received special emphasis since the late 1970s, aimed at aquisition of technologies emerging from universities and research centres. US counter-espionage is aiming to cut off as much of the hardware aquisition as possible. So, Inman predicts, US campuses will become the focus of a much intensive espionage. In 6 months, a year or 18 months, he warned at the hearing, it will become clear to everyone, including the Administration, how much the Soviet Union is benefitting from the "outflow" of information from the campuses on some sensitive topics. Pressure will then grow in the Administration to crack down on universities - unless by then, they themselves have controls in place.

Inman's role in this crusade is odd. In March, he repeated that he was not representing the CIA or the Administration and that his testimony had not been coordinated with the other Administration witnesses. He described himself as a self-appointed "goad" or "gadfly" to get people to think about the problem and to suggest "innovating ideas" for cutting down the "outflow" from their laboratories to the Soviet Union. The trouble with his case, so far, is that few university scientists seem convinced there is a large outflow or "haemorrhaging" of information about very high speed integrated circuits, robotics or anything else. Inman admits his case rests on evidence contained in a classified report that cannot be released without compromising intelligence sources. But representative Albert Gore Jr (Democrat, Tennessee), chairman of the committee's sub-committee on

investigations and oversight, who has seen the classified report, ventured at the hearing that the full evidence is not all that convincing. Inman himself conceded that "In an open society, there is a tendency to automatically (sic) take the view that one cannot debate the substance of issues unless you see the evidence." He and the Administration should understand that the discussion of what the universities should do cannot begin until the evidence is on the table.

The Administration's new-found zeal for secrecy about academic research has already had some tangible consequences. Some months ago, on the eve of a visit planned for a Soviet robotics expert to the United States, the Administration asked Stanford University and some other places to close their electronics laboratories to him. The universities replied that they could not police their visitors, whereupon the would-be visitor was not issued with a visa. The truth is that US universities cannot easily act as espionage policemen, especially when they are trying to forge links with industry to give US industry an "outflow" of

Visitor: Here's \$250,000 to spend. No strings. Just let me be the first to know.

Scientist: Hey! Don't you have relatives in Eastern Europe? How do I know you're not a spy?

Visitor: That's none of your business. Anyway, I'd been thinking of making a deal with that competitor of yours in Berkeley. How do I get out of here?

research results it badly needs to stay competive with Western Europe and Japan. Does Inman really want US scientists to be suspicious that every foreign visitor or industrial benefactor may be a spy? (See box.) Can it be wise to breed such suspicions when university scientists are making their first fragile attempts to reach outside their laboratories?

In reality, however, the issues the Administration has raised with the campuses offer much middle ground and room for discussion. University scientists already live with a spectrum of controls — from peer review to federal regulations — that appear not to inhibit academic freedom. More and more people are learning about the new shadings of controls required when dealing closely with industry — the distinction, for example, between teaching only basic science in the classroom and keeping possible patentable discoveries off limits for a certain period. Moreover, the Administration is engaged on several reviews that could have enormous impact on university research. The Commerce Department is reviewing the International Traffic in Arms Regulations (ITAR), passed in the Cold War era of 1955 (and which is probably unconstitutional), that allows the government to prevent to the export, and possibly publication, of "technical data" - whatever that is. At the hearing in March, in chilling testimony, Assistant Secretary for Trade Administratrion in the department, Lawrence J. Brady, said that in the past, it has not been fully understood that ITAR applies to all segments of US society, including the universities. George Millburn, an undersecretary at the Department of Defense, testified that a "struggle" is going on in the department to define which technologies are militarily important and subject to review and control. Yet the only academic involvement in these discussions is some work by the Defense Science Board and a study by the National Research Council of the National Academy of Sciences

0028-0836/82/160693-02\$01.00

(see page 695).

While there may be room for discussion, there are also the makings of a fight. Many academics or their champions, such as Gore, see in the Administration's words a threat to fundamental inquiry. Gore told Inman "we don't want to even (sic) take the first step along the road that has made Soviet science so pitiful". Inman, on his side, complained that the press and some academics misrepresented his statements to mean that he wanted to "throw a net over the public". Yet some universities have already taken avoiding action. At Stanford University the Faculty Senate has approved a resolution urging the university to resist interference with free scientific communication.

Academics are highly sensitive to any threats to their independence and tend to cry foul when anyone suggests they submit to any authority whatever — be it university administrators trying to enforce government accounting rules or suggested self-censorship of militarily important research. Moreover, President Reagan's military build-up and talk of nuclear war is stirring antagonism at many US campuses, as the recent wave of teach-ins and meetings attests. It would be all too easy for these issues to be rolled into one ball of wax in many academics' minds: burdensome federal regulations, arms build-up, nuclear war and government controls to prevent espionage. The resulting feeling would be that the Administration is against the universities and does not understand them — a feeling reminiscent of some campus attitudes towards former Presidents Johnson and Nixon. Given its penchant for loose, inflammatory rhetoric on other matters, the Administration may find it too easy to characterize campus resistence to controls as unpatriotic. The push from the right would then shove the campuses left. If the Administration keeps to Inman's timetable, the universities will have to step briskly—and calmly and rationally—to avoid an open conflict.

Big Brother's law

The British Government seems indifferent to its electors' needs for protection from data banks.

The British Government has simply failed to understand why there is public anxiety that computerized records may be a threat to people's privacy and, thus, liberty. That is the most charitable reading of the white paper on the subject, now at last published.* A more cynical, but probably more accurate, interpretation is that the government is squarely out of sympathy with the fear that computerized data banks may infringe the rights of individuals for which reason it will continue to drag its feet on legislation, doing everything it can to ensure that the eventual law is the bare minimum necessary to comply with the Council of Europe Convention signed a year ago.

The grudging character of the government's intentions can be told from the only statement in the white paper of the reasons why legislation is necessary. This mean document correctly records that the Council of Europe convention will require its signatories not to transmit personal data files to countries without satisfactory legislation, notes that this restriction could be a threat to international companies operating in Britain as well as to British computer bureaux and therefore concludes that "in order to conform with international standards of privacy protection and to avoid possible barriers to trade", the government will introduce legislation that will "enable the United Kingdom to ratify the convention".

Shabbily, nowhere is there a flicker of acknowledgement that the protection of people's privacy is in itself desirable, a public good of the kind which governments are elected to cultivate. Indeed, the government's sense that it owes something to its electors is expressed only in the repeated promise that the cost of administering the promised legislation will be kept to a minimum, and will be no charge on public funds. Even the salaries of the proposed registrar of personal data banks and his staff will be recovered from the fees that must be paid by their operators. Individuals seeking to verify the accuracy of personal data on

specific computer files will have to pay a fee "based on the principle that the costs for the demands are fully recovered". Those who, having paid their fees, think they have found their privacy to have been illegally infringed will have to mount prosecutions off their own bats, and at their own expense.

The government that happens historically to owe its existence to the Magna Carta, one of the earliest public declarations that tyranny is unacceptable to ordinary people, appears to be willing that ordinary people should take their chances in the courts if they have reason to believe that some injustice has been done by a data bank or those who operate it. Fortunately — this at least must be the hope — even the government's supporters in the House of Commons will be so affronted by what is now proposed that the unseemly legislation the government plans belatedly to introduce (not this year, perhaps not even next year) will be constructively and radically amended.

This is how libertarians in the House of Commons and elsewhere should argue. While computerized data banks are in principle no different from systems of records manually kept, they are potentially so much more efficient that their common use is tantamount to a qualititative change. So much has been acknowledged in the past decade by two government committees set up specifically to consider questions of privacy — the Younger committee (which reported in 1972) and the Lindop committee (reporting in 1978). False data, inadvertantly or even maliciously erroneous, can be damaging to those concerned. But even accurate data can be damaging, especially in the hands of those for whom they were not originally compiled. While it may be proper that information about people's dealings with tradespeople should be available to others in the same line of business, information such as this may be unwarrantably damaging in the hands of others, potential employers for example. Similarly, information about a person's medical history collected by one government department in the course of its legitimate business may be damaging when transferred to

So how should this transfer of data between different kinds of users be regulated? In its declaration of the principles on which the new legislation will be based, the British Government merely quotes the principles on which the European convention has been drawn (the chief of which is that a person should have access to any files about him, and the power to correct them if inaccurate or to erase them if illegally compiled). What needs to be decided, now and not later, is the basis on which the transfer of data may be allowed from one potlential user to another. It is simply not good enough to say that "it is expected that most applicants will be registered without question, but the Registrar will have power to make enquiries, to inspect data files and to require modifications to a system. In extreme cases, he may need to refuse registration. . .". What the government has so far failed to explain is how the registrar will decide which applications for registration are acceptable "without question".

The issue is especially important where the transfer of information between government departments is concerned. The European convention permits the exclusion from regulation of data banks "protecting state security, public safety, the monetary interests of the state or the suppression of criminal offences". This form of words is a sufficient licence for Big Brother. On the face of things, it will for example allow people's income-tax returns to be compared with their income from holdings of government securities or their applications for driving licenses to be checked against the records of the National Health Service, while the police will presumably be allowed to gather information from where they can in the cause of crime prevention. Are all these applications of data banks to be blithely sanctioned? By its repeated references to the European convention as the guiding principles on which the registrar will work, the British Government seems to intend just that. Parliament should insist that the European convention is not the final touchstone of what is permissible, but merely the starting point for what is bound to be a long and acrimonious argument.

Oppenheimer case boils up again

Files show FBI bugged pre-trial conversations

Washington

A forthcoming history of science journal reveals new information on the celebrated Oppenheimer case — the most traumatic incident in post-war US science — that suggests that the government stacked the case against Oppenheimer in proceedings that caused the revocation of his security clearance and his personal disgrace.

Physicist J. Robert Oppenheimer led the Los Alamos atomic bomb project during the Second World War. Afterwards, he was the unquestioned leader among US physicists seeking to shape the post-war world. Oppenheimer was influential in the debate over civilian control of atomic energy and, later, chairman of the General Advisery Committee of the Atomic Energy Commission (AEC). Oppenheimer was then without doubt the government's most influential science adviser.

But doubts about his possible pre-war Communist associations, and his apparent evasions in relation to them, led AEC to conduct an inquiry into his suitability to hold security clearance, and to a hearing before a specially appointed triumverate of AEC's Personnel Security Board in 1954. The hearing, including the testimony of his one time colleague Edward Teller, destroyed him.

An article by Barton J. Bernstein, Professor of History at Stanford University, in Historical Studies in the Physical Sciences*, to be published later this spring, alleges that despite President Eisenhower's stated wish that the government should conduct the inquiry in a dignified manner, commensurate with Oppenheimer's stature, the Federal Bureau of Investigation (FBI) nonetheless bugged Oppenheimer's conversations with his attornies before the inquiry and passed the transcripts on to prosecutor Roger Robb. AEC chairman Lewis Strauss personally thanked the FBI for their help in supplying the transcripts. "It would be an uneven contest", even before the hearing, writes Bernstein, "just as if one army had stolen its enemy's secret plans".

Moreover, Bernstein says, while members of the board and the prosecution had access to secret FBI files on Oppenheimer (some of which were unopened at the time that the government had given Oppenheimer earlier security clearances), these were never shown to Oppenheimer or his attornies on the grounds that security clearance could not be obtained in time.

These and other revelations are based on documents declassified by the FBI, the Department of Energy (successor to AEC) and the Eisenhower Library at Bernstein's request. But Bernstein believes there is still more to learn about the case, as "more than half" of the FBI material on Oppenheimer remains classified.

The chairman of the three-member panel that finally judged Oppenheimer a security risk was Gordon Gray, former president of the University of North Carolina and former Secretary of the Army. Gray's papers, unearthed by Bernstein, show that Gray considered the other two members of the board to be completely prejudiced against Oppenheimer before the hearing even started. The three sat down together beforehand, to go through the files. Grav wrote of the other two, "It seemed to me from the beginning that Mr Morgan and Dr Evans both had a strong hunch that Dr Oppenheimer's clearance should not be reinstated . . . During the weeks spent reading through the files this notion became much clearer." Evans made anti-Semitic comments, saying that he found "that nearly all subversives were Jews". "At the time I was concerned at this note of clear prejudice", Gray wrote. But he did not tell AEC that the board's members were not impartial as AEC rules required.

Bernstein's new documents also reveal that Edward Teller, whose testimony was crucial, had told the FBI some years earlier of his doubts about Oppenheimer, and that Teller's statements helped shape the charges. Teller, however, has said that he was undecided about Oppenheimer until the night before he testified, when Robb showed him Oppenheimer's security record.

But in 1952, according to Bernstein's article, Teller told the FBI that he would do almost anything to separate Oppenheimer from the General Advisery Committee because Oppenheimer had cleverly shifted from one argument to another on the committee and used his considerable influence over other scientists to delay development of the hydrogen bomb. In 1952, Teller had not said that Oppenheimer was disloyal, only that he was dangerous because he gave bad advice. To Teller in 1952, Bernstein writes Oppenheimer "was devious but not disloyal". He had persuaded Hans Bethe to refuse to work on the H-bomb and had swayed Henry D. Smyth, an AEC commissioner, to oppose it.

Bernstein believes that his new information also provides an even more "alloyed" portrait of Oppenheimer himself than has emerged in previous writing about the case, which has tended to portray Oppenheimer as a martyr. The documents show, Bernstein writes, evidence of "a string of lies and evasions" regarding his past, and that Oppenheimer had not always been candid with the authorities or his associates. Commenting on the strain that Oppenheimer visibly underwent at the hearing, Bernstein writes:

Oppenheimer was struggling to preserve his reputation . . . He lost. And he may have been under an additional strain that his defenders did not appreciate, for he may also have been hiding his former membership in the Communist party. Chevalier claimed that Oppenheimer had been a member, and Robb reached the same conclusion.

However, except for wondering what is in the yet unopened files, Bernstein says there

Merck backs UK neuroscience

Dr Leslie Iversen, director of the Medical Research Council's neuro-chemical pharmacology unit at Cambridge for the past eleven years, has been appointed director of a new laboratory being established in Britain by Merck, Sharp and Dohme. The new laboratory, which will be a going concern on a greenfield site near Harlow, Essex, by 1984, will be exclusively concerned with basic drugoriented research in the neurosciences and will eventually employ 200 people, a third of them with research degrees.

The British scientific community is delighted at this development, chiefly because of the jobs it will provide for researchers but also because it is a token of continuing American interest in the United Kingdom as a base for major research laboratories.

Dr Iversen said earlier this week that he was looking forward to the job, but emphasized that while the new research centre would concentrate largely on basic neuroscience, it would be an integral part of the company's research effort and thus different from the Roche research centres in Switzerland and the United States. The hope, he said, was that basic neuroscience research would suggest novel classes of therapeutic drugs.

The only cloud on the horizon is the future of the Medical Research Council's unit, which is to be decided in June this year and which has been for some years one of the brightest feathers in the council's cap. Dr Iversen says that he is anxious that the unit should survive his departure on 1 March next year, for which reason he intends to avoid recruiting any of his present staff until the council has made up its mind. Apart from the unit's basic research, it also houses the United Kingdom "brain bank" from which authenticated samples of brain tissue are distributed to qualified investigators.

^{*}Historical Studies in the Physical Sciences, Office for the History of Science and Technology, 470 Stevens Hall, University of California, Berkeley, California 94220 USE

is no direct evidence in the new material that Oppenheimer had indeed been a Communist.

Deborah Shapley

Soviet radio-catastrophe

Another theory

Washington

What did happen in the southern Ural mountains in 1957–58? Did buried radioactive waste explode? Or was the landscape blighted and thousands of people hurt by a strange weather pattern that rained fallout from Soviet atomic bomb tests in the north?

The disaster has been a mystery since it surfaced in the West in a Copenhagen newspaper report in 1958 that implied that a Soviet weapons test had gone awry, and speculation grew into controversy in 1976 when Zhores Medvedev, a prominent Soviet dissident scientist living in London, alleged there had been a catastrophic, volcano-like explosion from buried nuclear wastes in a secret area near the city of Kyshtym.

Now a new theory has been advanced by the Los Alamos Scientific Laboratory, that links the disaster, among other things, with acid rain. The public summary of a classified report concludes that there was no single catastrophic explosion of buried wastes, and certainly not an explosion involving nuclear criticality. Instead, widespread damage to the land and population was caused by "a series of relatively minor incidents . . . severely compounded by a history of sloppy practices" at a plutonium production plant.

The new report confirms the allegations of Medvedev and Soviet scientist Lev Tumerman, who drove through the region in 1960, in their horrid accounts of burned people and devastated land. It recounts that there were "death squads" of radioactively contaminated prisoners assigned to work in the area, essentially until they dropped dead.

The site of the alleged disaster was a plutonium production plant built for the Soviet weapons programme east of the city of Kyshtym on the site of a munitions plant that operated under the Tsars. The plutonium plant was apparently built in the late 1940s, after the Smyth and Groves reports had been published explaining how the United States had built its atomic weapons during the war. The report indicates that the Soviet Kyshtym plant was modelled on the US plutonium plant at Hanford, Washington, and that, the Soviet Union had detailed information about Hanford practices and procedures. The evidence for this, however, is not given.

So, the report says, a city was built having "thousands" of workmen and engineers. A graphite-moderated, uranium-fuelled reactor was built, called "Unit O". Cooling water from Unit O was pumped into a large artificial lake dug on the grounds. Later, the cooling water from

Rorvik disowned

New York

Dr Derek Bromhall, formerly of the University of Oxford, has won his suit against journalist David Rorvik and the publisher Lippincott and Company, On the third day of the trial this month (see Nature 1 April, p.383) and before a single scientist had taken the witness stand, the defendants settled out of court. The settlement is important not only because it amounts to a public disavowal by the publishers of Rorvik's book, published in 1978 under the title In His Image: the Cloning of a Human, but also because it is a precedent for other complaints of the unauthorized use of scientific data in popular works.

In an apology to Dr Bromhall which accompanied the settlement (said to amount to some hundreds of thousands of dollars) Martin H. Lippincott, Chief Executive Officer of the publishers, conceded that "this company now believe the story to be untrue" acknowledged that "Dr Bromhall did not consent to the inclusion of his name or his research techniques in the book and also that Dr Bromhall never engaged in, or attempted to engage, or advocated the cloning of a human being. We regret any embarrassment, humiliation, or other injury to him that the reference to Dr Bromhall in the book might have caused".

Lippincott and Company had promoted the book, about an unnamed American millionaire financing the birth of his clone, as non-fiction.

Judge John Fullam of the United States District Court, who had been hearing Dr Bromhall's suit last year, called the book "a fraud and a hoax". Apparently Lippincott began withholding royalty cheques from Mr Rorvik as soon as the initial suit began.

As Dr Bromhall is no longer an academic scientist, the direct damage to him from the book where his cloning techniques were quoted would have been difficult to prove, according to observers. Only the threat of punitive damages forced the hasty end to the trial.

Michael Stein

at least two reactors built there was also pumped into the lake. Fuel-rod cladding failures were probably frequent, the report says, so the rods leaked material. By 1953, the lake had become dangerously radioactive.

The lake fed into the Techa River, a slow-moving stream along which lived a primitive Bashkir people. Soon, the Techa, too, became "a chronic, waterborne source of radioactive contamination" long before any of the dates of alleged disasters. To separate plutonium from the irradiated fuel elements would have needed nitric acid. The off-gas belched yellow smoke out from a high smokestack, 24 hours a day for

years on end. Because of the high humidity of the region, the Los Alamos theory goes, the nitrogen oxides in the gas-would have produced acid rain and acid-laden snow which could have caused the "dead" landscape seen by Tumerman.

The Soviet Union was in such a hurry to get as much bomb-grade material as possible that the irradiated fuel elements were not allowed to cool, so the gases from the plant would have included radioactive iodine as well. The authors of the report say that the impact of the consequent acid rain would have been appalling. A third source of contamination was the burial of radioactive wastes from the late 1940s and the 1950s. The wastes were not put in steel tanks as at Hanford but radioactive liquid waste was simply dumped into a dry lakebed 5 or 6 kilometres south-east of the plutonium complex.

People in the Techa River region began having radiation sickness, crops were killed by acid rain and the stackgases. So, the report says, the authorities must have evacuated the Bashkirs and burned their homes. This would account for the burned buildings, and for the disappearance of local villages — signs Medvedev interpreted as indications of a nuclear disaster.

The Los Alamos report, like others, confirms that the landscape of the region was changed mightily in the late 1950s. The report includes "before" and "after" maps showing that new lakes were created, drainage canals dug to circumvent other lakes, and so on. All this, it seems, was necessary to stem the contamination of the Techa.

If there were explosions, the report concludes, they would have been chemical, not nuclear. Likely causes cited include ammonium nitrate and hexone, a flammable solvent often used in waste separation.

The report is the latest in a chain of Western "explanations" for the disaster. Curiously, one of the report's two authors, Danny Stillman a Los Alamos staff member, was a co-author of an earlier Los Alamos report attributing the disaster to fallout from "dirty" atomic weapons tests to the north at Novaya Zemlya, and a meteorological fluke that dumped the fallout southwards. Stratton was not available to discuss why the theory has changed: nor was the other author, Diane M. Soran. However, Harold Agnew, a former Los Alamos director who is president of General Atomic Corporation, and who coauthored the Novaya Zemblya theory, says the new theory is an improvement.

The proponents of the buried nuclear waste explosion theory are not convinced. Medvedev says that the report is simply wrong. The people who lived in the area were not simple Bashkir tribesmen as claimed in the report — the Bashkir Republic is somewhere else: the villages that disappeared after the disaster all have Russian names, and therefore had Russian inhabitants.

Moreover, Medvedev says his notion all

along was that the nuclear waste had heated and exploded thermally, or perhaps chemically. Especially during the first two years, nuclear wastes can heat up and possibly explode, unless they are carefully cooled. Medvedev notes that his theory, and a study published by the US Oak Ridge National Laboratory in 1980, conclude there was a single, major disaster on the basis of the ecological literature — evidence that the Los Alamos report ignores.

The Los Alamos report asserts that the incident is relevant "in the light of the current nuclear waste disposal questions facing the United States" but does not explain just how. But it implies that even when nuclear wastes were disposed of in the sloppiest manner imaginable, they caused no single catastrophe. Deborah Shapley

Britain in space

Up, up and away

The British government, not usually enthusiastic about spending public money, seems keen to find the cash for a major national programme in remote sensing. Members of a "task force" who have spent the past six weeks working out the details, were putting the finishing touches to their report earlier this week.

Behind the government's enthusiasm is its wish to make the best use of the European Space Agency's (ESA's) Earth Resources Satellite (ERS1) to which it has already pledged £28 million, or 13 per cent of the cost. Britain does not seem to be the only country to find an interest in remote sensing. All ESA's 13 member states are expected to meet next week's deadline for pledging their contributions to the satellite, even though it will be built under ESA's optional applications programme.

Assuming that the money is forthcoming, ERS1 will be a preoperational ocean-monitoring satellite following along the lines of Seasat, the United States equivalent, which hinted at the usefulness of looking at the oceans in microwave before it went out of service after only three months.

Thus the three instruments that will make up the ERS1 payload — a synthetic aperture radar, a wind scatterometer and a radar altimeter — will all record in the microwave band. The satellite's low polar orbit will give it global coverage for measuring such variables as wind speed, wave height and polar ice cover. Data are expected to be of use to the scientific community, weather forecasters and shipping and offshore oil companies.

Britain's singular interest in ERS1 was stimulated last month when a team from the Science and Engineering Research Council's Rutherford Laboratory won a competition to design a fourth instrument for the payload — an infrared scanning radiometer to measure sea-surface temperature to within half a degree Kelvin.

But the instrument, costing about £1 million, must be built with British money.

If the general level of interest is anything to go by, however, the Rutherford team has little cause for anxiety. The "task force", which includes representatives from the Science and Engineering Research Council, the Natural Environment Research Council, the Meteorological Office, the Royal Aircraft Establishment at Farnborough, industry and the Department of Industry, has been drawing up plans for a far grander national remote sensing programme that could involve spending more than £4 million. The report addresses three questions: the content of a programme of fundamental research into understanding microwave data; how to get the data to the user; and how to exploit commercially remote sensing in general.

The most costly consideration could be that of disseminating data from ERS1. ESA plans to set up a central ground receiving station at Kiruna in Sweden from which data can be relayed to agencies in individual nations. But the British study describes several options for a national ground station that could receive data directly from the satellite. These range from a £4 million station capable of receiving 120 megabits per second from the synthetic aperture radar to a much cheaper station capable of handling data at no more than I megabit per second. The cost would almost certainly have to be met by the industry department, which may try to persuade industry itself to chip in.

The data-handling part of the national programme could ride on the tide of the British government's general enthusiasm for information technology, so that it is no surprise that the report will be placed before Kenneth Baker, minister for information technology. The other important aspect for the government, however, is how to make money out of what is widely heralded as a growing international market. One option that the industry department is considering is to persuade private industry to set up a company to sell remote sensing data, as well as hardware and software for ground stations and satellite payloads.

The final details on the form of the national programme will probably take some months to work out. In the meantime, the plans seem to beg two questions. Are remote sensing data sufficiently attractive for potential users to pay for them? And is Britain, which has no national space agency, sufficiently well organized. On the first point, the industry department seems aware that it will be treading in the dark. But an earlier survey of more than 100 potential users has persuaded it that the risk could be worth taking, especially for ocean monitoring. And the civil servants who have been debating the merits of a national space agency for some time, could be encouraged by a decision to embark on a remote Judy Redfearn sensing programme.

Polish universities

Warsaw's rector

Poland's Council of Ministers has resumed consideration of two bills aimed at restructuring Polish higher education, apparently undismayed that the replacement of Dr Henry Samsonowicz as rector of Warsaw University is regarded in academic circles as a confirmation of growing fears for the future of scholarly life.

Dr Samsonowicz became rector in September 1980, under a compromise arrangement between the old system of government appointment of rectors and the promised reform by which the rector would be elected by the academic community. Subsequently, he was confirmed in office by a free election in which academics, students and university auxiliary staff were represented.

Since the imposition of martial law, Samsonowicz has been under increasing pressure and, according to some sources, was temporarily detained during the round-up of intellectuals in the first few days after the military take-over. A few weeks ago, he was expelled from the Polish United Workers' Party, since when his dismissal has been thought to be only a matter of time.

Nevertheless, the announcement that Dr Samsonowicz's "resignation had been accepted" caused a major wave of protests by Warsaw academics and students. At one point, all lectures were stopped in Warsaw University for 15 minutes to allow students and staff to sign protest letters.

The new rector, selected by the Minister of Science, Higher Education and Technology, is Professor Lazimierz Albin Dobrowolski, head of the department of zoology and ecology. In spite of the unfortunate circumstances of his appointment, Professor Dobrowolski does not seem as severe a hard-liner as some pessimists have assumed.

In a discussion on the proposed reforms of academic life in November 1980, he accepted as necessary the demands for reforms at all levels of education. He even implied that, theoretically, the universities already possess the right to make changes in their syllabuses which, if true, would make many of the reforms promised by the Lodz accords of February 1981 merely a restatement of powers which the universities already possessed but had not used.

With martial law, the reforms were cancelled and university life reverted to the statutes of 1958, which place full administrative power in the hands of the rector and reduce university senates and faculty councils to a merely consultative role. Many features of the pre-Lodz syllabuses, including compulsory Russian, have been restored.

How far the proposed new law will embody these "temporary" measures is not clear. As early as last summer, the then minister, Dr Jerzy Nawrocki, tried to emasculate the promised bill by last minute amendments which he introduced unilaterally. At that time, the minister's action was thwarted by the threat of a nationwide university strike. Strikes, of course, are now illegal under martial law.

Planetary science

Going downhill

Washington

Ever since Mr George A. Keyworth II. the President's science adviser, made some remarks to the effect that it had already had its day, planetary science has been struggling to find favour in Washington. Its trials are continuing, for its traditional patron, the National Aeronautics and Space Administration (NASA), is cutting back support, and it is not clear that the National Science Foundation (NSF), the logical alternative patron, will take up the slack. Although much more than hardware is involved, the controversy centres at the moment on the imminent closure of the relatively new Infrared Telescope Facility (IRTF) atop an extinct volcano on Mauna Kea, Hawaii.

Clearly, the entire field of astronomy is not going to get everything it wants from the government. For instance, a major study for the National Academy of Sciences (NAS) of future astronomical needs, chaired by George Field, director of the Harvard Smithsonian Center for Astrophysics (see *Nature* 8 April, p.482), has produced a list of desirable future facilities requiring \$1,700 million in expenditure over the next decade. The problem, however, is how to set priorities — a task scientists are reluctant to take on, with the result that it falls to the budget men in Washington.

Earlier this year, the Office of Management and Budget (OMB) told NASA that it could have only two of its three major efforts in astronomy. NASA opted to keep the space telescope, scheduled for launch in 1985, and the science programme for the space shuttle. This means that NASA's third major effort, planetary science, must suffer: the Earth and Planetary Sciences Division of NASA will be cut by half in 1983 compared with 1981, if the proposed \$61 million cut is not restored when Congress considers the NASA budget later this year.

The cuts affect funds that support young graduate students entering planetary science and astronomy, and small grants to astronomers around the United States, away from major facilities. Among the programmes axed was the Venus Orbiting Imaging Radar (VOIR) and funds were not restored for a US Halley's comet probe to complement the Giotto project. Moreover, although support for the solar-polar mission has risen to \$21 million, the increase supports only American work aboard the European spacecraft.

But the most conspicuous cut in the fiscal 1983 budget was the IRTF, which sits 13,000 feet above sea level on Mauna Kea. The IRTF was a pioneering facility built by NASA to observe the planets as support for Voyager and other missions. Its tasks include monitoring volcanism on Io and plotting the infrared signatures of the outer planets and their possible moons.

Axing the IRTF was not an arbitrary decision. All NASA facilities are supposed to support actual missions, and no US spacecraft will encounter a planet until Voyager reaches Uranus on 24 January 1986. Moreover, according to a policy statement made some years ago, all ground-based telescopes funded by the government should be supported by NSF, the government's basic research agency.

On 1 January 1983, the IRTF will be homeless, patronless and mothballed unless Congress restores its \$1.7 million annual operating cost in the NASA budget. NASA has recommended that NSF picks up this tab, but the NSF budget for 1983 is more or less set. Mauna Kea's administrators will have to file a proposal to NSF to get the money — but even then may well not succeed.

John T. Jeffries, director of the Institute for Astronomy at Mauna Kea (which includes other facilities besides the IRTF), is urging Congress to restore the funds to NASA. For the moment, Jeffries says he is reluctant to ask NSF for the money, which at this late stage could come only from other astronomers.

If the telescope goes, United States astronomers would have no national centre for infrared work — either within the Solar System or outside it. The infrared facilities at Wyoming and Arizona serve mostly local astronomers, while a comparable facility on Mauna Kea, the United Kingdom Infrared Telescope, is available mainly to British astronomers.

The Mauna Kea IRTF's plight is typical of the dilemma facing much of the basic science carried out by mission agencies in the United States. The facility is built and operated by NASA, so dedicates half its work in support of NASA's planetary exploration programme. But applications to work on objects outside the Solar System, such as the gas clouds of Orion, are more than double IRTF's applications for planetary work.

But whatever the merits of Mauna Kea's IRTF or the fate of Jeffries' attempts to save it, the issue not being discussed is the one Keyworth raised originally, of whether planetary science has had its day and deserves lower priority than other branches of astronomy. According to Field, chairman of the NAS study, "traditionally, NASA has tried to encourage cooperation rather than conflict between planetary research and galactic and extragalactic astronomy. It has not allowed them to come into conflict but has maintained constituencies for both."

Deborah Shapley

Biotechnology

Dutch go-ahead

Waalre, The Netherlands

The Dutch have at long last got their "innovation programme" biotechnology, eagerly awaited since the beginning of the year (see Nature 14 January, p.91). A government-sponsored committee under the chairmanship of Professor R.A. Schilperoort, who works on recombinant DNA research at the University of Leiden, did not, as might have been expected, recommend setting up new centres for biotechnology along the lines of those planned in microelectronics. Instead his committee has opted for the rapid strengthening of cooperation between government institutes, universities and industry.

The committee urges that the government should provide extra support to stimulate innovation in biotechnology — at least an extra 75 million guilders between now and 1988. This money would come from the government's fund for industrial innovation and be in addition to the planned biotechnology budget, which is much larger.

Efforts should be concentrated on applied research, the committee concludes, especially in sectors where Dutch companies are traditionally strong — such as agriculture, the dairy industry, fermentation and antibiotics production. Areas highlighted for future research include the development of host-vector systems for use in applied research, somatic cell hybridization, second-generation biotechnological reactors for enzyme production and the isolation of useful products from process liquids.

Professor Schilperoort is confident that the existing large and medium-sized Dutch companies (such as Shell and Unilever) will be better able to tackle the challenge than would newly-formed small companies. Discussions on the regulation of recombinant DNA research went on in The Netherlands for far too long. Professor Schilerpoort believes, badly holding up research; "The discussion should stop now. There certainly must be rules, but not stricter than necessary or stricter than in other countries. Permits to start work should be issued quickly, and the rules should be established nationally. Rules made by regional safety authorites have sometimes been too strict.'

Schilperoot, who himself sometimes acts as an adviser to a foreign company, says that Dutch industry and universities often have extensive contacts abroad at the expense of national cooperation. "Better structures here would create a favourable climate that would encourage more confidence in this field and put The Netherlands in a strong position in 5 years' time and have a great impact on society and industrial activity in the next 10 to 20 years."

Casper Schuuring

Shake-up plans for National Academy of Sciences

Washington

This week, the US National Academy of Sciences (NAS) holds its annual meeting in Washington. Probably more than 300 distinguished scientists will gather. They will not transact much business of substance, but there will be much chat about the Academy's reorganization and the new vision of things of its President, Frank Press, a geophysicist who was President Jimmy Carter's Science Adviser.

The NAS is old by American standards (it was founded by President Abraham Lincoln in 1863) and has been accused of being old-fashioned, especially when it tries to give the government the definitive word on such controversial topics as marijunana use or ozone or acid rain. Clearly the academy's science panels have had difficulty giving advice when the assigned topics have been of emotional national concern. "Most of what the academy has done in the past has been extremely good and very important," says Press. "But if we do fifty reports well and one report badly, often the one report gets all the attention.

Press wants to retain NAS's reputation for fairness, impartiality and as the country's most authoritative source of science advice. He wants to continue the special relationship the NAS has long held as the government's science advisory group. But he wants reports to come out faster, review procedures to be simpler, and the NAS to exercise leadership in what topics are studied by having independent sources of income to fund self-initiated studies.

These views have already had their effect. Several key studies were initiated, either with Press's advice before or after his taking office, which are half or less fully supported by the government. Among them are:

 University research and national security headed by Dale R. Corsen, former president of Cornell University. It is due to report in a year;

"DON'T TALK TO ME ABOUT AGEING!"

 Government relations with research universities, led by Burke Marshall, professor of law at Yale University. It will study indirect costs, Circular A-21, federal regulation of the laboratory, and will report this summer;

 Relations between the industrial democracies in an era of high technology competition, led by Howard Johnson, Chairman of the corporation, MIT. It is due to report by the end of 1982;

 Arms control and international security, led by Marvin Goldberger, President of California Institute of Technology;

 Ageing. This study is just getting under way. "The government wasn't interested in supporting this" says Press.

Press has started to raise money for NASA's endowment, most of which was raised by former president Frederick Seitz and which now stands at about \$30 million. Three foundations have given \$3 million so far and a fourth, the Alfred P Sloan Foundation, has agreed instead to help fund the government-research university-study. Meanwhile, NAS's sister organization, the National Academy of Engineering and the Institute of Medicine (IOM), are starting fund-raising drives of their own.

Press is also planning to seek funds from industry through a corporate affiliate programme. "People will say how can you separate donations from control of the work" Press said, anticipating criticism of this move. "We plan to have companies put their membership fees in a blind pool, which we could then draw on without corporate advice to fund our work." In return, member corporations would be invited to special symposia and get all academy reports.

Press, conscious of criticism that academy reports come out slowly and that review procedures are cumbersome, intends to have a special management procedure for the 20 or 30 reports that are nationally significant, thus ensuring that they are "timely" and "dependable".

The studies could be revised faster — "a review should not take more than 2 or 3 months" says Press. Usually, the board overseeing a study does one review of it; then it goes through an separate review procedure run by the National Research Council, NAS's research arm. Press is experimenting with having both reviews go on at once or having the board waive its review if it has a say in the review run by NRC. Another way to speed up reports is not to insist on consensus, but to let dissenters express their views separately. "I've encouraged that", Press says.

To "simplify" NAS procedures, Press is abolishing all the assemblies set up by Handler ten years ago, and two of the future commissions. An *ad hoc* panel under James Ebert, president of the Carnegie Insitution of Washington, looked

at the academy structure and recommended changes, most of which have been implemented by NRC in the past month or so (see *Nature* 1 April p.385).

Under the "streamlined" NAS organisation the old established offices such as the Transportation Research Board and the Office of International Affairs will become their own bosses again, their parent commissions abolished or merged with other things. Agriculture is given new priority, and will probably become its own research board. More attention will be paid to primary and secondary level technical education by the Commission on Behavioural and Social Sciences and Education. What will happen to the

Frank Press - businesslike approach

Institute of Medicine and the Assembly of Life Sciences is uncertain, although there will probably be a new life sciences commission, excluding agriculture. Oceans activities will be consolidated from four boards into two.

Press can implement these changes without a vote of the membership and indeed has already done so. One reason he is seeking non-government money, he says, is to stabilize the staff situation; he plans to hold more regional meetings of members. While most members have accepted the changes, and probably welcome the additional outside funds, Press's business-like approach to the academy has aroused some murmurs — especially from people in commissions being abolished.

Deborah Shapley

Correction

Professor E.A. Barnard, not Professor B. Hartley, is head of the biochemistry department at Imperial College, London (*Nature*, 1 April page 382). Nature apologises to both professors.

CORRESPONDENCE

University role

SIR — Your analysis in Science in France (Nature 25 March, pp.285-304) prompts me to respond, especially on the subject of the role of the universities in the research effort.

First, your articles clearly transmit the French media's impression that the best research in the country is done outside the universities in the grand organismes research centres. Nothing could be further from the truth: many of the most prestigious groups of CNRS and INSERM are directed by university professors (such as P. Chambon, J. Dausset, J.F. Bach, M. Seligmann . . .), and they are also closely involved in the training of future investigators.

Many CNRS and INSERM laboratories are actually located in university campuses, and research teams usually include both university staff and CNRS and INSERM appointees. In addition, many of the CNRS, CEA and INSERM laboratories located outside of the campuses are staffed in part by university faculty. Thus at the Institut Pasteur or at Institut de Recherche en Biologie Moléculaire from the CNRS, a number of teams are directed by university professors, actively involved in the training of the students of the various investigators.

A second point arising from your articles is the future role of the universities in research. The faculties of sciences have been heavily involved in both research and training in the past and will continue to be so. This does not go without a rigorous selection of potential candidates, a fact which remains generally unnoticed by the media: our own "UER de Biochimie" (Unit for Eduction and Research in Biochemistry) has about 700 undergraduate students: only 70 are admitted to the graduate courses in microbiology, virology, immunology, molecular biology and nutrition. The first three of these courses are organized by the University of Paris's staff on the premises of the Institut Pasteur.

Incidently, most of the graduates will end up in CNRS and INSERM research, not only because no new openings are available at the universities but also because these students are the best trained in the field — a fact which we would like our new ministers to be aware of.

A. DONNY STROSBERG

CNRS Institut de Recherche en Biologie Moléculaire, Université Paris VII, Paris, France

Mosquito war games

Sir — In his report (Nature 11 March, p. 104) about allegations of American biological warfare research in India and Pakistan, Dr K.S. Jayaraman is altogether too modest in omitting mention of his own primary role in the press campaign on this topic in India in 1974-75. That campaign was long ago shown to have been based on incorrect information and erroneous reasoning (Nature 252, 342; 256, 355; 258, 102; 273, 96). However, as a result of the atmosphere of suspicion created by that campaign all sorts of difficulties are still put in the way of international collaborative work in India on topics of vital importance to the Indian people, such as nutrition and malaria.

Jayaraman correctly states that yellow fever

does not occur in India and he suggests that the only reason to study the "yellow fever mosquito", Aedes aegypti, would be in support of biological warfare. However, as he was told in 1974, Ae. aegypti is also the vector of dengue and dengue haemorrhagic fever in India and elsewhere. He was always inclined to belittle the importance of these diseases but certainly Literaturnaya Gazeta does not do so, and one of its more bizarre claims was that mosquitoes were being reared in Pakistan and transported to the Caribbean area for use in biological warfare against Cuba, using dengue virus.

It has been claimed that work was planned or carried out at the Pakistan Medical Research Centre (PMRC) on genetic manipulation of Ae. aegypti and on Japanese encephalitis virus. However, Professor R. Baker, ex-director of PMRC, the Annual Reports of PMRC and our own research visits there make it quite clear to us that this was not so. A small amount of work was done on West Nile virus which is indigenous to Pakistan. This work was to study the feasibility of producing a mosquito strain not susceptible to transmission of this virus. Such work may lead to vector control by the introduction of nonsusceptibility genes into wild mosquito populations. The main work of PMRC was on methodology for Anopheles and Culex control by release of semi-sterile males and several elegant genetic sex separation systems were developed to ensure that only males were released. Male mosquitoes do not bite and therefore could not possibly be the agents of biological warfare.

PMRC has produced a remarkable amount of excellent published work. It would be a shame if the history of the WHO/ICMR unit in Delhi should be repeated and the work of PMRC were hampered or terminated as a result of ill-informed and prejudiced journalism.

London School of Hygiene and Tropical Medicine, London WCl and Tsetse Research Laboratory University of Bristol, UK

Propaganda wars

Sir - Yet again a leading article your journal (1 April, p.380) disparages the work of Scientists Against Nuclear Arms, the Medical Campaign Against Nuclear Weapons and other groups of professional people dedicated to reducing the present dangerous accumulation of nuclear weapons. The charges brought against these groups seem to be the following: They can only partially address the problem and offer no practical advice; they claim a spurious unity among the profession concerned; they are prone to oversimplifying the issues; and finally, their influence is somehow "irrational". These charges are no more than risks (some more real than others) to be avoided. They are not sufficient reason to condemn the existence of these groups. Perhaps a paragraph's explanation may allay fears that the emergence of these groups is unhelpful or even dangerous.

Education is obviously a place where the informed should act — not individually but in

groups which can bring the information to the public more effectively. This is made even more necessary by the fact that the government's own literature on nuclear questions seems bent on misinformation and deception. As scientists, we have an especial responsibility to inform the public not only because of our knowledge of relevant scientific matters but also because of our understanding of the armaments industry and the complex ways in which technology, warfare and politics interact. Thus, aware of the dangers inherent in the present situation, we need effective representation of our views. This is provided by the professsional groups which are now being formed. Moreover, it is essential to the disarmament movement that it is seen to be as widely based as possible, including professional people as well as parents, Christians, politicians and so on. Diversity here is strength, not weakness.

There are many of us, well informed on the present situation, who are convinced that we shall die within the next few years in a nuclear conflict unless the course of current events can be turned. There are a few signs of hope however, one of which is the emergence, rapid growth and energetic activity of the professional groups that you misguidedly choose to malign. I ask that your journal supports the work of these groups so that mankind can again be confident of its future.

D.E. RYDEHEARD A. MYCROFT

Edinburgh University, Edinburgh, UK

Sir — Your editorial of 1 April ("Professional propaganda", p.380) concludes that groups such as Scientists Against Nuclear Arms, Teachers for Peace and the Medical Campaign Against Nuclear Weapons are deceitful and intrinsically undesirable because they foster the false impression that their professions are united on the issue of nuclear weapons, and because they do not address the relevant issues. This is a contentious inference based on dubious assertions, and it is unusual for Nature to adopt a deliberately provocative and weakly argued position so firmly. This political use of your unique position in scientific journalism seems to me a more egregious abuse of professional influence than the overtly political activities of the scientists and other groups that you have attacked in JULIAN PETO

The Radcliffe Infirmary, Oxford, UK

On the flat

Sir. — M. Hammerton (*Nature* 18 March, p.192) asks why you continued so long to publish letters on creationism, arguing that you would not give such space to flat-Earthers, for instance. But on the same page is a long letter from Professor J. W. Jeffery, citing, as the core of his argument, an unpublished study of his own and a 1979 work of sci-fi and crystal-gazing in energy technology as if it were a work of economic fact.

Surely it is time we heard from the flat-Earthers.

DAVID FISHLOCK

Financial Times, London EC4, UK.

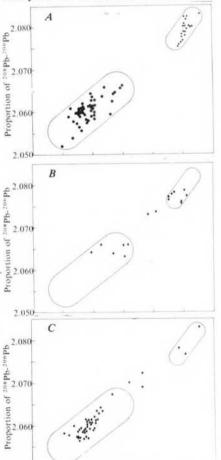

NEWS AND VIEWS

Lead isotopes and the Bronze age metal trade

from Keith Branigan

For the past twenty years archaeological scientists have spent much time and effort trying to trace the metals used by early man back to the ore sources from which they were originally recovered. Attention has been concentrated on the possibilities of identifying characteristic patterning of trace elements in the metal. Research published within the last twelve months by Noël and Zofia Gale of Oxford University, however, has shown that successful provenancing of metals is now possible by using lead isotope analysis. Preliminary results have already produced some major surprises about the supply of metals to the civilisations of the Aegean Bronze Age $(\sim 2000-1200 \text{ BC}).$

Despite the production of many thousands of trace element analyses, both archaeologists and archaeometallurgists have remained sceptical of the successful application of this method to the provenancing of ancient metals. The chemical composition of ores seems to vary within the same ore body, and early smelting techniques resulted in poorly controlled changes in concentrations of trace elements in the metal they produced. An alternative method has therefore been sought by Noël and Zofia Gale, working from the Department of Geology and Mineralogy at Oxford. Their studies have concentrated on lead isotopes which have two important characteristics. First, the lead isotope composition of different lead ores differs according to their geological age and the amounts of uranium and thorium initially present. Thus a lead ore body can be 'finger-printed' by isotope analysis. The second significant characteristic of lead isotopes is that their composition pattern is not altered by the metallurgical processes. This means that not only ores, but also objects made of lead, silver, or other metals containing lead can also be 'finger-printed', and related directly to an ore source. Five years of research enabled the Gales to publish the 'finger-prints' of various Aegean leadsilver sources in June 1981 (Scient. Am. 244, no. 6, 176), and to announce the isotope analyses of about 90 Bronze Age artefacts of lead and silver from the same region. The analyses of ores revealed that lead-silver ores from the islands of Siphnos, Antiparos and Syros, and from the site of Laurion in Attica could all be clearly distinguished by their varying isotope composition patterns (Fig. A). The analyses of artefacts immediately

0.828 Proportion of 207 Pb. 200 Pb.

A, isotope analyses of lead ores from Siphnos (triangles) and Laurion (circles) cluster in two quite distinct groupings (simplified from Gale & Gale 1981). B, lead isotope analyses of 16 lead artefacts from the Cyclades, ∼ 2500 BC, show 8 were made of Siphnian lead, 6 of lead from Laurion and 2 cannot yet be provenanced. C, analyses of 46 lead/silver objects from Crete and Thera (Cyclades) show that by ∼ 1500 BC, almost all objects were made of lead from Laurion on the Greek mainland (field at bottom left).

produced a major surprise - the importance of the Laurion lead-silver source in early Aegean metallurgy. Its significance to classical Athens is well known and documented, but no one had believed that its metals had been extensively used 1.000 years earlier. In fact, the Gales' analyses showed that even in the early Bronze Age 2.000 years before classical Athens the Laurion mines supplied silver and lead to the islands of the Cyclades, the rest of Cycladic silver and lead coming mainly from Siphnos (Fig. B). In the second millennium BC, the Siphnos source was scarcely used and lead and silver throughout the Cyclades and Crete, as well as on the Greek mainland, came mainly from Laurion (Fig. C). But Laurion silver and lead travelled even further afield, for among the artefacts analysed by the Gales were six from Egypt, all of which proved to be made of the distinctive Laurion lead and silver. The earliest of these items dates to the 10th Dynasty, about 2100 BC, and supports other archaeological evidence which points to an opening-up of Aegean trade with the east Mediterranean in the centuries either side of 2000 BC.

At the 5th Creteological Congress in September 1981, at Ayios Nikolaos, Crete, the Gales presented two further papers (not yet published). Zofia Gale described new isotope analyses for lead-silver ores from Crete (characterized in each case by a very high 207 Pb/206 Pb ratio) and also some 40 new analyses of Minoan lead-silver artefacts. They showed that whilst most of the early Bronze Age items in Crete were made of Siphnian lead/silver, a few items of Laurion metal were already reaching the island. Again, this supports the evidence of imported mainland pottery at Knossos around 2500 BC, and of Minoan-style (if not Minoan-exported) trinkets at Ayios Kosmas in Attica at the same period. One major controversy remained unsolved by the analyses - the origin of three silver daggers found at Koumasa in Crete, and variously claimed as Italian, Cycladic and Minoan in manufacture. Zofia Gale's analysis of one of these daggers showed it was made of neither Siphnian nor Laurion metal; its origins cannot yet be determined.

Noël Gale's paper to the Congress and a newly published article in *Science* (216, 11; 1982) are potentially the most significant

Keith Branigan is in the Department of Prehistory and Archaeology, University of Sheffield, Sheffield S10 2TN.

for archaeology world wide, however, for they present the first analyses of copper and bronze artefacts by the lead isotope method. Copper and bronze were used for far more artefacts in antiquity than was lead or silver, and in much of prehistoric Europe, for example, lead and silver were scarcely known. Gale's demonstration that the amounts of lead found as an accidental inclusion in coppers and bronzes is sufficient for isotope analysis opens up wide possibilities of identifying prehistoric metal trades with confidence for the first time. Copper sources used by the Minoan bronzesmiths have been the subject of much debate, and Italy, Crete and Cyprus have all been proposed, with Cyprus the undoubted favourite in the late Bronze Age. Gale has analysed copper ores from Crete, Cyprus and Laurion and established their isotope composition patterns. The first batch of 22 copper/bronze artefacts analysed, all from Crete, surprisingly suggested that there were perhaps four

different ore bodies producing the metal from which these objects were made. although the location of only one of them can yet be fixed — and that is Laurion! Half of the objects analysed come from Laurion, which has never previously been thought of as a potential source of copper for the Aegean civilisations. None of the artefacts was definitely of Cypriot origin, and this result, preliminary as it may be, must raise afresh the old controversy over the famous ox-hide ingots of copper. Found in Cyprus, Crete, Turkey, central Greece, Sicily and Sardinia, and shown in Egyptian tomb paintings, these heavy slabs of copper clearly represented a major Bronze Age trade in metal. But did they go from the west Mediterranean to the east, or from the east to the west, or from the centre to both west and east? Most favoured a Cypriot origin, but Gale's analyses carry at least one clear message - we must think again, and await more analyses, before we can finally solve the problem.

Cooperation and conflict in breeding groups

from N. B. Davies

In over one hundred and fifty species of birds, some individuals forgo breeding and, instead, assist others to feed and care for offspring. Such 'helping at the nest' is as an example of 'altruism' because the helpers increase the reproductive success of the breeders at a cost to themselves. Field studies of marked individuals have shown that, in many cases, the helpers are previous offspring of the breeders and stay at home to help their parents raise more broods. Because the young in the nest are close relatives (often full sibs) a helper does increase its gene contribution to future generations through helping. But why doesn't it adopt the alternative option of leaving home and breeding?

Charnovi has pointed out that most birds have biparental care and two individuals, a disperser plus its mate, could normally rear more young than one alone. By leaving home and pairing up a bird could raise more offspring (coefficient of relatedness, r = 0.5) than it could by staying alone at home and helping to raise extra full sibs (where r is again 0.5). If it stays at home a helper thus forfeits half of its potential brood — the offspring its mate would have reared. Are there, then, ecological conditions which might force young birds to stay at home? Two recent papers by Emlen^{2,3} examine the ecological correlates of helping in birds and provide a model for the evolution of social behaviour in breeding groups.

Helping occurs in a wide variety of environmental conditions. Brown⁴ was the first to point out that individuals are more likely to remain on their parental territory in very stable habitats where populations have expanded to the carrying capacity of the environment so that very few breeding vacancies exist. Good evidence comes from studies of the acorn woodpecker, Melanerpes formicivorus. In coastal California the habitat is extremely saturated and during a three year study⁵ no breeding vacancies arose. On average there were five adults per territory because many young had stayed at home to help their parents. By contrast, in the more seasonal Huachuca mountains of south-eastern Arizona there were many vacant territories and most young dispersed and bred⁶.

Helping at the nest also occurs at the opposite ecological extreme, in very harsh and fluctuating environments, such as the arid areas of Australia and Africa, where rainfall, and hence food supply, is very variable and unpredictable. Emlen² suggests that during harsh periods the costs of leaving to rear young are prohibitive for novice breeders and so many stay at home until conditions improve. Measurements show that young white-fronted bee-eaters, Merops bullockoides, stay at home and help their parents when the insect food supply is low, but in times of plenty they leave and breed themselves.

At first sight it would seem that helping at the nest should be a truly cooperative affair; the breeders gain through help with their brood while the helpers increase their inclusive fitness through raising siblings.

N.B. Davies is a Demonstrator in Zoology at the University of Cambridge and Fellow of Pembroke College.

However, Emlen³ goes on to show that there are often conflicts of interest in these breeding groups and he defines the precise circumstances when these will occur. Sometimes the young will increase their chances of survival by staying on the parental territory but the parents will suffer because of increased competition for resources. In this case the young could decrease the costs of their presence by helping as 'payment' for permission to stay. Breeder-helper conflict will be intensified when r between the helper and the nestlings is low (for example, because one or both of the breeders have been replaced). When there are few outside vacancies helpers may be expected to challenge breeders for breeding rights in the group. There is good evidence for this kind of conflict in pied kingfishers. Cervle rudis, where some individuals offer to feed the breeders' offspring with fish but are often chased away. Here the helpers (who are unrelated to the breeders) may be offering food as a payment for access to the breeding female as a potential mate⁷.

In theory, conflict can also occur in the opposite direction. Emlen suggests that this will be especially prevalent in fluctuating environments where, when conditions for breeding are good, the helpers do better by leaving home. From their parents' point of view, however, they only rear grandchildren (r=0.25) if they leave, whereas if they stay they help the parents to raise more children (r=0.5). Forceable retention of helpers may be impossible but the breeders could, in principle, manipulate circumstances in their favour by disrupting the breeding efforts of their dispersed young so that they came back home to help instead. Trail, Strahl and Brown⁸ report destruction of nests and eggs and the murder of nestlings in groups of Mexican Jays, Aphelocoma ultramarina. In these examples, the murderers were unrelated to their victims but the effect is similar to that envisaged by Emlen. Helpers in the Jay groups may feed the young in several nests at once and so a possible benefit of the infanticide is that it increases the number of helpers available for the killer's own nesting attempt.

Emlen provides an elegant explanation for why there is both conflict and cooperation in breeding groups and the behavioural evidence is in qualitative agreement with the theory. To test the model quantitatively, however, we need to be able to calculate the precise reproductive payoffs to breeder and helper if the helper stayed or if it left. All these calculations to date have relied on measurements of natural variation in the population. For example, if groups with helpers have greater success than groups without, the difference is regarded as the helpers' contribution. In a similar vein, the reproductive success of a novice breeder is regarded as a measure of what a helper would achieve if it left home and bred. The problem of using observations on natural

variation to quantify the parameters in the model is one of confounding variables. Helpers which leave home and breed may be better-quality individuals than those that stay at home. Pairs with helpers may be better-quality breeders than those without; indeed, if the helpers are previous offspring, then their presence may be a consequence of the breeders' high reproductive success in the past rather than a cause of present success.

Experimental manipulations are needed to quantify the helper's contribution and the payoffs it would achieve by leaving home. Field workers are understandably reluctant to carry out large-scale manipulations of their study populations because this interferes with the long-term collection of data on natural success. Brown and his co-workers9 have now reported the first removal experiment of helpers in the grey-crowned babbler, Pomatostomus temporalis. Groups with helpers removed did worse than control groups, showing conclusively that the helpers themselves increase reproductive success.

Further experiments of this kind are needed, particularly as different explanations are likely to emerge in different situations. An intriguing case is that of the dunnock, Prunella modularis. where pairs plus a helper have lower reproductive success than pairs without¹⁰. Before we jump to the conclusion that the 'helpers' must in fact be hindering the pair, a removal experiment is needed. An alternative possibility is that helpers only manage to force themselves on to territories with poor-quality breeders; the breeders may have done even worse without the helper!

Finally, it is interesting to note that cooperative breeding often occurs in groups of unrelated individuals. In the Mexican Jay11, unrelated immigrants help feed other pairs' nestlings and defend the territory in the same way as close relatives. With all the recent emphasis on the role of kin selection in the evolution of social behaviour we may have underestimated the importance of mutualism and reciprocation (see ref. 12). In this issue of Nature (p.740), Packer and Pusey show that there is just as much cooperation in unrelated coalitions of male lions as in related groups. Although a male would increase its inclusive fitness even more by cooperating with a brother, it still pays to cooperate with non-relatives simply because large coalitions father more surviving young per male than small coalitions.

from J.M. Rhodes

IF basaltic magma, produced by partial fusion of the Earth's mantle, were to rise through the mantle and overlying crust, ultimately to be erupted from some volcano with no change in composition, it would be avidly sought and studied by petrologists and geochemists intent on deciphering the composition and mineralogy of the mantle. Basaltic magmas such as these, which have made their way to the Earth's surface without change in composition, are usually referred to as 'primary magmas' since they are the parental compositions from which other, more evolved magmas are produced by a variety of processes as the magma cools. crystallizes and ultimately solidifies. They are regarded as a sort of Rosetta Stone to the Earth's interior, and, indeed, to the interior of any planet, providing suitable samples are available.

However, there is little agreement on whether a primary basalt has ever been sampled, and their nature and composition remain subjects of spirited debate even after almost twenty years. With the advent of the plate-tectonics hypothesis, basalts that have been erupted along the vast 65,000 km interconnecting, spreading midocean ridge systems have figured prominently in this debate, and discussion has mirrored the arguments concerning primary magmas in general.

On the one hand, typical mid-ocean ridge basalts are considered the best candidates for primary magmas because of their vast volumetric abundance, which exceeds the products of more conspicuous forms of volcanism by an order of magnitude, coupled with an apparent world-wide compositional uniformity1-3. Alternatively, and currently favoured, is the argument that mid-ocean ridge basalts, and indeed almost all basalts, are far removed from primary compositions, being instead the end products of an extensive and complex differentiation process from a primary picritic magma; a process that may include crystallization, contamination and mixing with other magmas, as the magma makes its way to the surface through the fractures, conduits and chambers of the volcanic plumbing system⁴⁻⁶. Somewhere between these two extremes is the view that only the most primitive basalts sampled from the ocean floor are primary⁷⁻¹⁰.

All these interpretations have their difficulties. Most mid-ocean ridge basalts show both mineralogical and chemical evidence for crystallization at shallow levels within the crust, an observation clearly at odds with a primary status. Objections to the primary nature of 'primitive' basalts come from melting

experiments, which show that their compositions are at variance with the picritic melt compositions predicted to form at depths of over 30 km in the mantle. The absence of picrites amongst samples recovered from the ocean floor is a major obstacle to their acceptance as primary magmas, and has led to a number of cunning models which attempt to explain why these picritic magmas cannot rise through either the crust or a pre-existing magma chamber!1-13.

These difficulties, and those of identifying primary magmas and understanding the processes that relate them to the commonly erupted mid-ocean ridge basalts, are addressed in a recent comprehensive paper by Bryan and coworkers14 dealing with the compositional variations of basalts erupted along the Mid-Atlantic Ridge adjacent to the Kane Fracture Zone. In contrast to most papers on the subject, Bryan et al. argue for a spectrum of primary magma compositions, rather than a single magma type from which all other ocean-floor basalts are derived. They identify at least two distinct compositions that are parental to most other basalts in the Kane Fracture Zone region through complex interaction of crystallization and magma-mixing processes10,11,15. One of these parental compositions is not unlike the proposed 'primitive' basalt primary magma. Although not abundant, it can be recognized as an end-member component in a number of mixed magma compositions. The other, more widely distributed parental magma does not have a 'primitive' composition, and is, in fact, close to estimates of average mid-ocean ridge basalt compositions¹⁶.

Of these two parental magmas Bryan et al. believe that the 'normal' rather than the 'primitive' variety is the more appropriate candidate for a primary magma, thus contrasting with the recent preference for elusive, if not illusory, primary compositions, and returning to the idea that primary magmas should be abundant and widely distributed, and parental to the less abundant, evolved basalts associated with them¹⁷. They point out that although this suggestion may appear at odds with chemical criteria commonly used to identify primary magmas, it is not contradicted by evidence from melting experiments^{6,18,19}, providing the magmas formed at shallow levels in the mantle. The 'primitive' parental basalts, on the other

hand, are much less abundant, and do not correspond in composition with experimentally predicted mantle melts produced at any depth. Bryan et al. suggest that these 'primitive' basalts are not primary, but are the differentiates of the elusive primary picritic magmas.

Thus, they envision a wide range of possible primary magma compositions, depending on the depth of formation and segregation from the mantle. The corollary to this is that compositionally similar basalts may have been produced in quite different ways, either by direct melting of the mantle or through differentiation of a more primitive melt en route to the surface. This last point may explain the apparent paradox that while compositional criteria require massive amounts of crystallization to produce evolved basalts from 'primitive' or picritic magmas20, phenocryst assemblages and melting experiments commonly point to a much less extensive process. However, others have explained this same paradox as a consequence of mixing 'primitive' magmas with more evolved ones in crustal magma chambers^{15,21}

In keeping with the controversial nature of the subject, it is unlikely that the scheme presented by Bryan and co-workers for primary basaltic magmas from the Kane Fracture Zone region will win universal acclaim. If correct, it has several important implications. Perhaps the most immediately disquieting, particularly to geochemists, is the realization that the commonly used compositional criteria for identifying potential primary magmas may be of little value. More far-reaching, however, and an aspect not explored by Bryan et al., is the implication that if some of the 'normal', widely distributed oceanfloor basalts are primary and not evolved, then substantial portions of the sub-

oceanic mantle must be a more fertile source of melts, and richer in iron and incompatible trace elements, than popular mantle models suggest. Whatever one's prejudices, it is clear that the concept of multiple primary magmas will receive more attention in the future. In the paper under discussion the authors argue for primary magmas that are either picritic or widely distributed normal mid-ocean basalts as a consequence of melting at various depths in the mantle. Others appeal to schemes of incremental melting of increasingly refractory mantle in an ascending diapir to produce primary magmas with differing compositions^{8,22,23}. To resolve these increasingly complex concepts, careful and comprehensive major, trace, isotopic, petrographical and experimental melting studies of samples from well documented basaltic terrains will be needed. If these are forthcoming, perhaps the primary magma controversy will have disappeared after the next twenty years.

Interferon redux

from Robert M. Friedman, Lois B. Epstein and Thomas C. Merigan

An international symposium on the chemistry and biology of the interferons*, held a few weeks ago, saw rapid progress reported in four main areas of investigation: structure and function of interferons (IFNs) and their genes, animal and in vitro models for IFN action, IFNs in human diseases, and clinical trials with recombinant and natural IFNs.

Charles Weissman (University of Zurich) reported that 14 different genes for human IFN-a are now known, 3 pseudogenes have been sequenced, and 4 others are known that hybridize but, as yet, have not been sequenced. He has now cloned mouse IFN-a, and suggests that, whereas the genes for IFN-α and IFN-β seem to have diverged some 400 million years ago, those for human and mouse IFN-α diverged about 70 million years ago. D. Goeddel (Genentech Inc.) has cloned four genes for bovine IFN- α and he and his colleagues have also cloned IFN-y in Escherichia coli and monkey cells and achieved its cloning and partial secretion in yeast. The gene has three introns and four exons and is located on human chromosome 12.

Natural IFN-y has been purified to homogeneity (J. Vilcek, New York University School of Medicine) and is found in 20 and 25,000 molecular weight forms. 125 I-labelled IFN-y binding studies show the receptor for IFN-y and IFN-β to be the same, but distinct from that for IFN- α . In preliminary antiproliferative studies on HeLa eells, pure IFN-y was no more potent than IFN-α. High-level production of cloned IFN-\(\beta\) (M. Innis, Cetus, Berkeley) is associated with distinct morphological changes in the producing bacteria.

Recombinant IFN-α has crystallized by Weissman's group and by S. Pestka (Roche Institute) and his colleagues, but X-ray diffraction studies have yet to be used to elucidate the tertiary structure of the molecule. From the location of hydrophobic and hydrophilic

*The symposium on "Chemistry and Biology of Interferons: Relationship to Therapeutics" was held on 742 March 1982 at Squaw Valley, California. It was one of the 11th Annual UCL Symposiums on Molecular & Cellular Biology to be published by Academic Press, New York

residues, R. Wetzel (Genentech Inc.) predicted that IFN-a is a globular protein with a hydrophobic core, more than 65 per cent of which is in α -helical formation connected with intervening \(\beta\)-sheets. Both he and Pestka indicated that the last 11 amino acids of the recombinant A IFN are not necessary for its antiviral effect; in fact, Pestka and his colleagues have found three natural IFN-a molecules that are only 155 amino acids long, compared with most other IFN-a molecules which have 165 or 166 residues. Pestka argued that the potency of various IFNs should be defined in terms of the number of molecules necessary for achieving a given effect now that the availability of pure recombinant IFNs makes this possible. His and others' data make clear that various recombinant IFNs have different degrees of antiviral and antiproliferative activity when compared on a per molecule basis. Despite the differences, L. Epstein (University of California, San Francisco) showed that natural IFN-a and recombinant IFN-a (A) induce the same peptides in normal fibroblasts. Recombinant, like natural, IFN- α also induces 1.5-2 times as much of these peptides in fibroblasts trisomic for chromosome 21.

Several groups have inserted the genes for human IFN-β in murine cells and J. Collins and his colleagues (Gessellschaft fur Biotechnology) have found that at least five other genes are co-regulated with the IFN- β gene, but activation of these genes is not necessary for production of IFN-B in this heterologous background.

The antiviral and cell growth inhibitory effects of IFNs can be separated in a Swiss mouse cell clone that remains sensitive to the former, but has lost sensitivity to the latter (T. Sreevalsan, Georgetown University). IFN treatment was also shown to result in a decrease in ADP

ribosylation and in protein methylation. There was much discussion of the role of the IFN-induced protein kinase and 2',5'-oligoadenylate (2',5'-A,)-related systems in the actions of IFNs. The 2',5'-A_-activated endonuclease is important in determining the antiviral action of IFNs (I. Kerr, Imperial Cancer Research Fund). The endonuclease may also be important in IFN inhibition of cell growth: endonuclease activity was absent in human melanoma cells resistant to growth regulation by IFN, but present in melanoma lines sensitive to it (A. Creasey and T. Merigan, Stanford School of Medicine). The 2',5'-A, system may have other roles: the degree of natural killer cell activity in large granular lymphocytes was increased by transfection with 2',5'-A, (R. Herberman, NIH). P. Torrence (NIH) explored the significance of the IFN-induced kinase in inhibiting in vitro viral protein synthesis. Adding the double-stranded RNA, poly(A) poly(2'-fluoro, 2'-deoxyuridylic acid), that activates the protein kinase, but not the 2', 5'n-synthetase, to extracts of L cells does not cause inhibition of protein synthesis; although the same inducer inhibits protein synthesis in reticulocyte lysates. Several other model systems for IFN activity were presented. In mouse cells transformed by bovine papillomatosis virus, in which the viral DNA remained as an episome, the viral DNA copy number per cell was decreased by IFN treatment (P. Howley, NCI, and R. Friedman). After 10 passages morphological cell revertants, entirely lacking in viral DNA, were found. Such 'cured' cells could be again transformed by the virus.

IFNs were reported to be present in a variety of human diseases, but their origin and effects remain cryptic. An unusual species of acid-labile IFN-a is present in about 50 per cent of patients with systemic lupus erythematosis (SLE) and in male homosexual patients with Kaposi's sarcoma or lymphadenopathy (O. Preble, J.A. Sonnabend (NIH), R. Friedman & J. Vilcek). One SLE patient was found to carry antibody to human IFN-a. The glomerular basement membranes from the kidney of another SLE patient with membranous glomerulonephritis developed fluorescence when sequentially exposed to rabbit anti-human IFN-a and to fluorescent anti-rabbit IgG (S. Panem, University of Chicago). The latter suggested that immune complexes containing human IFN-a may contribute to the development of renal disease in SLE. Another morphological relationship between SLE and IFN was reported by S. Rich who found that tubuloreticular structures, that are induced by IFN treatment of human lymphoblastoid cells, are present in both SLE patients and human cancer patients undergoing IFN treatment. J. Hooks (NIH) described the in vitro production of IFN-y by the tumour cells of a patient with an OKT8-positive

Olivine transformed from J. Zussman

J.D. BERNAL (like W.L. Bragg) applied his knowledge of crystal structures to a broad range of topics and, as early as 1936, was able to suggest that the mineral olivine, (Mg,Fe),SiO₄, would transform to the spinel structure at the high pressures found deep in the Earth's mantle. There is now much evidence that olivine is the major constituent of the rocks of the Earth's upper mantle, so any transformation that occurs at greater depth is of obvious geological and geophysical importance.

In 1966, Ringwood and Major¹ produced the transformation in the laboratory (at about 1.000°C and 115 kbar) and found not one, but two, highpressure polymorphs, β- and y-Mg₂SiO₄. The higher-pressure y-phase does, as suggested, have the spinel structure and the β -phase a modified version of it. Analogous structures for Co,SiO4 were later determined by Morimoto et al.2. Density increases of about 10 per cent are associated with the transformations and probably explain the discontinuity in seismic P-wave velocity3 observed at a depth of about 400 km. The phase change with increased density may perhaps also be a driving force for the downward movement of slabs of oceanic crust at continental plate margins, and may act as a trigger for deep-focus earthquakes in these regions4.

The β - and y-phases have also been found in certain meteorites and are thought to have been produced by extraterrestrial - rather than Earth impact shock pressures. Studies of the Tenham chondritic meteorite by Putnis and Price suggested that the β -phase was metastable, but phase relationships in the system Mg2SiO4-Fe2SiO4 at high pressures and temperatures are particularly complex at the Mg-rich end.

J. Zussman is Professor of Geology in the University of Manchester, M13 9PL.

T-cell leukaemia, and C. Chany has (INSERM) found a variety of IFNs in human amniotic fluids. In addition, L. Epstein discussed several defects in IFN-a or -y production, but saw no reason for treatment of the immunological disturbances in these conditions with IFNs at present, or until there is further understanding of the role of IFNs in the pathogenesis of primary and secondary immunodeficiency diseases.

One purified recombinant DNAproduced IFN, a2, (Hoffman La Roche) stimulated low levels of antibodies in 10 out of 200 treated patients and in this respect, it resembles native IFNs. The National Cancer Institute's Phase 1 trials of recombinant IFN-a2 and lymphoblastoid IFN also indicate some antitumour activity in various human cancers. In contrast to other published results, an increase in natural killer cell activity could not be

It seems likely that the direct $\alpha \rightarrow \beta$ transformation, and also $y \rightarrow \beta$ and $y \rightarrow \beta \rightarrow y$ can all occur with increasing depth because the associated temperature increase enlarges the stability field of the β-phase6

In this issue of Nature (p.729), Price, Putnis and Smith now describe transmission electron microscopic studies of veinlets in the Peace River meteorite. The B-phase occurs in micron-size crystals as pseudomorphs of olivine and also replace ringwoodite (naturally occurring a-Mg,SiO₄). They identify defects in the ringwoodite as stacking faults which are, in effect, very thin sheets of the B-structure in the fault plane. They point out that the β - and γ -structures can, as a whole, be considered related by such stacking faults, and suggest that growth of the β -phase from the fault plane produces fault-free β -crystals. In the meteorite the \(\beta\)-phase is thus derived from the y-phase in a post-shock retrograde process occurring on reduction of pressure. This contrasts with the views of Madon and Poire7 that the faults in ringwoodite are associated with the prograde olivine to spinel transformation.

The authors round off with some speculation as to the relevance of the mechanism of transformation that they describe to a $\gamma \rightarrow \beta$ transformation in the Earth's mantle. They suggest that the systems of stacking faults involved might well be sensitive to external shear forces and thus pertinent to the rheological properties of the mantle.

demonstrated. Positive results in cancer patients also come from a French trial of IFN-β in which dosage level and scheduling were the minimum necessary to elevate natural killer activity in vivo. Preliminary clinical trials of IFN-B in Germany and Japan were presented, as well as studies of lymphoblastoid IFN produced by the Burroughs-Wellcome group. Gutterman (MD Anderson Hospital) reported a series of 19 renal cell carcinoma cases in which 7 patients showed shrinkage of disease with IFN treatment.

Two newly analysed randomized, controlled trials showed positive results. A group from Stanford observed that varicella virus infections in leukaemic children can be improved with IFN and M. Hirsch (Massachusetts General Hospital) reported that the impact of CMV infection on renal transplant recipients can be lessened with IFN-a prophylaxis.

Breaking the active galaxy speed record

from Andrew Lawrence

OBSERVATIONS of the variability of the light output of quasars and Seyfert galaxies have been of great importance as probes of the physical conditions in these 'active galactic nuclei'. New evidence has been reported! that the Seyfert galaxy NGC 6814 varies on the amazingly short time scale of 100 s, not only revealing the smallest dimensions so far for an active galactic nucleus, but at last beginning to place constraints on the physical processes responsible for the prodigious rate of energy output.

The time during which a body can change its behaviour by a significant amount is limited by the speed with which information can travel across the body; large bodies cannot alter as rapidly as small ones. The early realization that some quasars vary on a time scale of months² led astronomers to the astonishing conclusion that bodies that could fit comfortably between here and the nearest star are

emitting as much energy as an entire normal galaxy. The 1970s saw the discovery that quasars and Seyfert galaxies expend a large fraction of their energy budgets as X rays. Several experiments found cases in which X-ray production varied over days and even hours3-8. Such considerations have led to the common belief that X rays relate most directly to the actual 'central powerhouse' of active galaxies. The volume of space involved in such a fast variation is far smaller than can be directly resolved with either optical telescopes or even the largest baseline radio interferometer. Variability studies may thus extract information unobtainable by any other method

In 1978, controversy began over evidence presented by a group at Harvard⁹

Andrew Lawrence is at the Royal Greenwich Observatory, Herstmonceux Castle, Hailsham, East Sussex BN27 1RP. that the X-ray emission from the Seyfert galaxy NGC 4151 had varied on the remarkable time scale of 700 s. The data were rather marginal, and a group at the Goddard Space Flight Center (GSFC) published observations repudiating this suggestion⁵. However, a new study by Tennant *et al.*, from the same group at GSFC¹, has presented convincing evidence that a similar Seyfert galaxy, NGC 6814, varies its output on a time scale of 100 s.

Such very rapid variability tells us more than just the size of the radiating body. It places constraints on the parameters of models suggested to explain the activity of these galactic nuclei. Tennant *et al.* discuss several points in detail.

One hundred seconds corresponds to a light travel distance of 3×10^{12} cm. The X-ray emitter cannot be larger than this. If a massive black hole is at the heart of the business, it cannot be more massive than 10^7 solar masses (M_{\odot}); or the event horizon would be outside 3×10^{12} cm. On the other hand, to explain the observed luminosity by accretion of matter requires a black hole of at least $10^5 M_{\odot}$ Such a system can have been radiating at its present luminosity for

100 years ago

ILLUSTRATIONS OF NEW OR RARE ANIMALS IN THE ZOOLOGICAL SOCIETY'S LIVING COLLECTION

HARDWICKE'S CIVET-CAT (Hemigalea Hardwickii). — The Viverridae, or Civet-cats, form a well-marked family of carnivorous mammals peculiar to the tropics of the Old World, and mostly confined to Southern Asia and Africa, though one or two of them occur in the southern parts of Europe. One of the finest and largest of them is the True Civet-cat (Viverra civetta), from the anal glands of which the old-fashioned perfume known as civet is extracted, and the Genets, Ichneumons, and Mungooses are well-known members of the same family, examples of which are always to be seen in the Zoological Society's Collection.

Amongst the rarer and less familiar forms of the Viverrine groups is the very curiouslymarked animal which we now figure (Fig. 17) from a specimen received by the Society in October, last year. Hardwicke's Civet, though first described by Dr. Gray so long ago as 1830, is a very scarce and little-known species, and the present example is believed to be the first of its kind ever brought alive to this country. In 1840 Müller and Schlegel gave an excellent figure and description of this animal, under the name of Viverra boiei, in their great work upon the Natural History of the colonial possessions of the Netherlands. Their specimen was obtained in South-Eastern Borneo by Herr Henrici, and sent alive to the

Fig. 17. Hardwicke's Civet-cat.

Gardens of the Zoological Society of Amsterdam. Hence, after its death, it was transferred to the National Museum of Leyden. Müller adds that he never met with this Civet-cat himself during his extensive travels in the Eastern Archipelago, and had received no information as to its habits.

Hardwicke's Civet-cat was also figured and described by Eydoux and Souleyet in the "Zoology" of the voyage of the Bonite in 1841, under the name Hemigate zebra, but again without any information as to its habits,

not even the locality of their specimen being stated.

So far as has been ascertained from the Zoological Society's living specimen, this animal is excessively shy and retiring in disposition, and apparently does not leave its retreat voluntarily except at night. When handled, it ejects a highly acrid and skunk-like secretion from its anal glands. The length of the body in the example figured is about 24 inches, and that of the tail about 18 inches. From Nature 25, 608, 27 April 1882.

only 2 per cent of the currently accepted age of the Universe or it would have accreted more than its own mass. As approximately 2 per cent of all galaxies are active, the new evidence could suggest that all galaxies have an active phase for 2 per cent of their life times.

Much argument about X rays from active galaxies centres on the radiation mechanism involved. Is it thermal? Or is it due to very high-energy relativistic electrons (like those found in radio galaxies)? Such high-energy electrons must lose their energy extremely fast. Tennant et al. conclude that for such non-thermal mechanisms to be viable, some process must continuously re-accelerate electrons throughout the emitting volume. Are thermal processes simpler? Not really; the X-ray spectrum is consistent with optically thin thermal emission, but from such a small volume, thermal radiation should be optically thick. Thermal processes are only viable in more sophisticated models where very hot electrons give a 'boost' to UV photons inserted from outside the X-rayemitting region.

Why have such rapid fireworks not been seen from other objects? In another, as yet unpublished, investigation10, Tennant et al, find that of 30 objects studied, only NGC 6814 showed such behaviour. In other studies of Seyfert galaxies, only NGC 4051 and possibly NGC 3227 have shown variability on a time scale of minutes^{11,12}. All three galaxies are rather low-luminosity examples of the Seyfert phenomenon, but other low-luminosity objects have not shown very rapid variations. There are indications that these objects have anomalous optical and IR properties13, but the data are still scant and confusing.

Recently preprinted observations with the Einstein Observatory14 have claimed 100 s variability in the quasar 1525 + 227.The data are not as convincing as in other cases, but if confirmed, the new observations could be of great importance; the X-ray luminosity of 1525 + 227 is several hundred times that of NGC 6814, and the constraint placed on models would be correspondingly tighter. Hope for further progress in these matters in the near future rests on the performance of the European X-ray satellite EXOSAT, due to be launched in autumn 1982.

Receptors for T-cell growth

from D.E. Kipp and B.A. Askonas

THE study of lymphocyte mediators has recently become an active area of cellular immunology. Although it has been known for more than twenty years that conditioned media from lectin-stimulated spleen cells contain lymphokines which enhance in vivo immune responses^{1,2}, the more recent discovery that conditioned media can support the continuous growth of activated T cells in vitro3 has made the T-cell growth factor(s) (TCGF) of particular significance.

In vivo, the importance of TCGF lies in the control of T-cell clonal expansion and responses. In vitro, the use of TCGF has proved of enormous value since it has made it possible to select and grow T-cell clones with different functions, such as cytotoxic T cells or T-helper cells. For the first time, single clones of T-cell subpopulations of known antigen specificity can be studied. This has made it possible to characterize their phenotype and functions, and their release of various lymphokines, factors, or interferon; to type lymphocyte-defined human histocompatibility antigens; and to determine the fine specificity of individual T cells and their recognition of antigen in conjunction with products of the major histocompatibility gene complex. It has also made it possible to provide important sources of lymphokines.

The resting T cell is unresponsive to TCGF and presumably does not express receptors for TCGF on its cell surface. In contrast, mitogen- or antigen-activated T-cells respond to TCGF4 and continue to grow in vitro. In a recent report, R.J. Robb, A. Munck and K.A. Smith⁵ define receptors for TCGF by examining the binding of biosynthetically labelled TCGF derived from a human T-leukaemia cell line (JURKAT) to various cell types. TCGF was purified after incubation of JURKAT cells with radiolabelled amino acids to a single band on SDSpolyacrylamide gel electrophoresis at a molecular weight of about 15,000, equivalent to the previously estimated molecular size of human TCGF6. This was the only measure of purity, but the material was functionally active and its binding properties to cells paralleled functional activity. The authors estimated by equilibrium binding assays of the purified radiolabelled TCGF that there were 10-15,000 receptors on TCGF-dependent mouse cytotoxic or helper T-cell clones. Furthermore, while normal murine splenocytes and thymocytes as well as human peripheral blood cells showed just barely detectable binding of radiolabelled TCGF, alloantigen- or lectin-stimulated cells had

D.E. Kipp and B.A. Askonas are in the Immunology Division of the MRC National Institute of Medical Research, Mill Hill, London NW7 IAA.

easily detectable receptors. This result supports the observations that only antigen-or mitogen-activated T cells are responsive to TCGF, whereas unstimulated T cells (and lipopolysaccharideactivated B cells) are not reactive to TCGF and appear not to possess any receptors for TCGF

Robb et al. also studied the binding of radiolabelled TCGF to a variety of human neoplastic cell lines. All of the non-T-cell lines and 90 per cent of human T-cell lines failed to bind TCGF. The human T-cell lines have been classed as T-cell lines on the basis of rosette formation with sheep red blood cells and this may not be an ideal criterion. The absence of TCGF receptors may therefore be explained in several ways. The transformed cell lines may have lost expression of their receptors or may have been derived from early T cells that had not yet expressed receptors. Certainly, antigendependent untransformed T cells, be they helper or cytotoxic cells, can respond to TCGF7.8. The one human T-cell line found to bind TCGF, which apparently grows well without the addition of exogenous TCGF, has recently been shown to both produce and respond to TCGF9.

The work of Robb et al. also confirmed the specificity of the human receptor for TCGF. The binding of radiolabelled human TCGF to its receptor was not inhibited by any other growth factor tested or by TCGF derived from rodent spleen cells which does not act on human T cells. On the other hand-human TCGF is not species specific and acts on rodent T cells as well¹⁰. The association and dissociation of human TCGF binding to mouse cytotoxic T cells showed a rapid turnover of TCGF and its receptor as well as a rapid degradation of TCGF after association with its receptor. This rapid degradation may have an important regulatory significance as the presence of TCGF would allow for the continued expansion of activated T cells in the lymphoid tissues, and thus block any dampening of the immune response when it is no longer needed.

These studies provide insight into the regulation of the immune response by TCGF. However, it needs to be stressed that this is only the beginning of such studies. Clearly it will be important to define the nature of the receptor for TCGF and we thus await eagerly the next chapter of this unfolding story.

Shear stress in fault zones

from Barry Kean Atkinson

SINCE estimates of the shear stress acting on fault zones at major plate boundaries varv by at least an order of magnitude, such fundamental issues as the driving mechanism of plate tectonics and the energetics of crustal faulting remain entirely unresolved1. The shear stresses in the Earth's crust cannot be measured directly, except very close to the surface, so likely stress levels have to be inferred from various secondary lines of evidence.

Laboratory studies of rock friction generally predict that shear stresses on earthquake faults must be at least as high as 100 MPa, unless pore fluid pressures approach that due to the overburden. Such high pore fluid pressures may occur transiently during earthquake faulting through a shear-heating-induced thermal expansion of water² but an impressive array of data (summarized in ref. 3) shows that pore pressures much greater than hydrostatic will generally only develop in crustal rock sequences containing thick blankets of impervious rocks.

A different level of shear stress is indicated by seismological studies. The average stress drop in crustal earthquakes is usually of the order of 10 MPa, or less, irrespective of the strength of the earthquake source, implying that ambient stress levels are also of this order. The key evidence of long-term, low shear stress, probably around 10 MPa, comes from the absence of a heat flow anomaly around the Andreas Fault. A recent San comprehensive review4 of the latest heatflow data for the western US further supports this view. However, unless relative plate velocities are unreasonably high (tens of cm yr⁻¹), the metamorphic gradients and K-Ar ages of rocks along the Alpine Fault of New Zealand are consistent with shear-heating due to a much higher shear stress⁵, of at least 100 MPa.

Geological evidence from fault rock textures suggests that both high shear stress (100 MPa) and low shear stress (10 MPa) faulting occur in the upper crust, with the latter more common6. High pore fluid pressures are clearly involved in some low stress crustal faulting and higher shear stresses are usually associated with reverse faulting on dry immature fault zones (the Alpine Fault may be exceptionally dry⁷).

Even if earthquakes along plate boundaries often occur in an environment where ambient shear stress is low, it could be argued that intraplate earthquakes are different and occur where the ambient shear stress is higher. In the eastern US, for

Barry Kean Atkinson is in the Department of Geology, Royal School of Mines, Imperial College, Prince Consort Road, London SW7 2RP

example, some surficial rocks have higher values of deviatoric stress than are found in the western US, perhaps implying shear stresses of several tens of MPa at depth. In addition, the moment of earthquake faulting for a given length of fault break is about one order of magnitude higher in some intraplate regions of the US than in western California. The argument has, however, recently been demolished by Raleigh and Evernden⁸ — for the US at least. They point to some little appreciated facts.

First, attenuation rates of horizontally propagating seismic waves with frequencies relevant to intensity observations (1-4 Hz) are grossly different throughout the US. Second, the energy of intensity-relevant frequencies for earthquakes in the conterminous US is solely dependent on fault length and has no relation to attenuation. Finally, for a fixed length of fault break there is a very substantial increase in seismic moment for a change in attenuation from that typical of western California to that typical of eastern US. Thus, moment values have to be explained within models of the Earth that are highly heterogeneous.

These facts can be explained if earthquakes in eastern US occur along fault zones that constitute soft inclusions in an otherwise rigid and strong crust/mantle system. In order to calculate the true moment of an earthquake, allowance must be made for the effective dimensions of a volume in which stress relaxation occurs. Relatively high moments for short fault breaks are only achieved in association with a large volume of relaxation which can be larger than the inclusion. There is no physical anomaly implied by this result, merely a more heterogeneous earth model than is usually used in seismology.

Raleigh and Evernden⁸ also review the evidence for low shear stress on Californian fault zones and conclude that fault zones in all regions of the US are sites of low ambient shear stress and low stress drop.

Fault motion at low shear stresses has been supposed difficult because high pore fluid pressures have been thought to be the only way to reduce the frictional resistance of a fault. Recent research has shown, however, that the chemical effects of pore water may also have a significant effect.

It is notoriously difficult to run deformation experiments in the laboratory at strain rates comparable with those in tectonically loaded fault zones. Yet, such experiments are essential if the range of potential water-weakening reactions are to be assessed. A few years ago, it was shown that stress relaxation experiments9 could be used to assess strain rates on fault zones down to about 10-10s-1, within one or two

orders of magnitude of some tectonic strain rates but some five orders of magnitude slower than typical laboratory strain rates. Since then this technique has been applied to the study of stress levels on water-weakened faults in a range of crustal rocks10.

For faults in many wet crustal rocks a dramatic weakening occurs at strain rates below 10⁻⁷s⁻¹, probably due to some combination of stress corrosion and diffusional mass transfer. The effect is in addition to any strength reduction due merely to the mechanical effect of high pore fluid pressures. Additional support is given to the stress corrosion hypothesis by the observation that in quartz, the rate of crack growth increases by five orders of magnitude on raising the temperature from 20 to 200°C (ref.11).

Some of these experimental results can be extrapolated to conditions thought to occur at depths down to 15 km along the San Andreas Fault Zone, For sandstone and quartzite, shear stress for sliding under slow, tectonic strain rates of 10-11 to 10-14 s⁻¹ is of the order of 10 MPa, even if pore water pressure never exceeds hydrostatic. For granite, however, a modest pore water overpressure is required to lower shear stress for sliding into the 10 MPa range.

The explanation for diversity of shear stresses on crustal fault zones may lie in water's different mechanical, thermodynamic and, especially, chemical properties. There is sufficient variation both in the time scale of fault zone processes and in the material properties of crustal rocks which, given the diverse physico-chemical actions of water, could explain the range of shear stress estimates for fault zones. There is a strong case8 that the environment in which many earthquakes occur is of low shear stress, but with stronger asperities of varying sizes and density of distribution along the fault surface which account for less common, local shear stress of several tens of MPa.

Future work must concentrate on working out the details of potential chemical weakening effects of pore water on rock strength under simulated crustal conditions. Some reliable means will also be required for extrapolating laboratory experiments to the larger strains typical of slip on earthquake fault zones.

REVIEW ARTICLE

Atomic and gravitational clocks

V. M. Canuto*† & I. Goldman*

* NASA Goddard Institute for Space Studies, Goddard Space Flight Center, New York, New York 10025-7886, USA † Department of Physics, City College of New York, New York 11031, USA

Atomic and gravitational clocks are governed by the laws of electrodynamics and gravity respectively. While the strong equivalence principle (SEP) assumes that the two clocks have been synchronous at all times, recent planetary data seem to suggest a possible violation of the SEP. Our past analysis of the implications of an SEP violation on different physical phenomena revealed no disagreement. However, these studies assumed that the two different clocks can be consistently constructed within the framework. The concept of scale invariance, and the physical meaning of different systems of units, are now reviewed and the construction of two clocks that do not remain synchronous—whose rates are related by a non-constant function β_a —is demonstrated. The cosmological character of β_a is also discussed.

OF the forces of nature, the two more successfully described are the electromagnetic forces, through quantum electrodynamics (QED) and macroscopic gravity, through Einstein's theory of general relativity (GR). The high level of agreement between predictions and observations leave little doubt that we now possess the correct physical interpretation as well as the theoretical tools to describe both forces.

QED and GR are also complete theories in the sense that they yield operationally well-defined clocks which satisfy the dynamical equations of the theories themselves. To understand what is required for a theory to yield a well defined clock, we introduce the notion of scale invariance, SI.

Consider a dynamical equation defined in a given system of units, containing field variables and dimensional parameters. Consider now a scale (length) transformation of the type

$$L \to L_{\pm} = \Omega_{\pm}^{-1}(x)L \tag{1}$$

where $\Omega_*(x)$ is a dimensionless arbitrary function of space-time. Regarding coordinates as dimensionless space-time markers, it follows from equation (1) that

$$g_{\mu\nu}^* = g_{\mu\nu} \Omega_{\star}^{-2}(x), ds_{\star} = \Omega_{\star}^{-1} ds$$
 (2)

Furthermore, a physical tensor Λ of arbitrary rank will be taken to transform like

$$\Lambda \to \Lambda^* = \Lambda \Omega_{\pm}^{-\pi(\Lambda)} \tag{3}$$

where $\pi(\Lambda)$ is called the power of Λ : $\pi(ds) = 1$, $\pi(g_{\mu\nu}) = 2$. Because null cones transform into null cones, it follows that c = 1 holds in all systems of units. Therefore, because v = (v/c)c, $\pi(v) = 0$. The power of any quantity can therefore be expressed in terms of $\pi(m)$ and $\pi(L) = 1$.

Given these definitions, an equation is scale invariant if: (1) in the transformed system of units, it preserves the same form involving the transformed fields; (2) it has the same parameters; and (3) there is no explicit dependence on $\Omega_*(x)$

We now show that a SI theory cannot yield a unit of time, that is, a clock. Because of the assumed SI, the dynamical equations governing the clock are identical in any system of units and so their solution for the period p of the clock in one given system of units is the same in any other system of units, $p = p_*$. On the other hand, if instead of solving the dynamical equations, we apply the transformation (1) directly to p, we obtain the result $p = \Omega_* p_*$, that is $p \neq p_*$, in contradiction with the previous result. It follows that a SI theory yields a solution

that is simultaneously constant and variable, thus proving that such a quantity is physically meaningless. In other words, a SI theory, being invariant with respect to changes in scale, does not possess a scale, thus lacking an intrinsic unit of time.

Therefore, a SI theory cannot provide a clock. For a clock to exist, the underlying theory must be non SI.

As an example, let us consider the case of the electromagnetic clock, an electron revolving around a proton, governed by the following equations¹:

$$\frac{1}{\sqrt{g}}\left[\sqrt{g}F^{\mu\nu}\right]_{,\nu} = J^{\mu}, \qquad u^{\mu};_{\nu}u^{\nu} = \frac{e}{m}u^{\lambda}F^{\mu}_{\lambda} \qquad (4)$$

The periodic solution with the period p is given by

$$p = 2\pi \frac{m^2 l^3}{e^4} [1 + 0(v/c)^2]$$
 (5)

where l is the angular momentum per unit mass. In equations (4) there is a 'time coordinate' x^0 whose physical meaning is not given by equations (4), where x^0 is in fact a marker. Its physical meaning can be determined by considering that since $de/dx^0 = dm/dx^0 = dl/dx^0 = 0$, we have from equation (5) $dp/dx^0 = 0$, thus allowing one to attribute a physical meaning to x^0 . Equations (4) are therefore constructed so as to yield a physical unit of time, given by equation (5). This property is due to the fact that equations (4) are not SI. In fact, let us apply equation (1) to equations (4). As $2\pi(e) = \pi(h) = 1 + \pi(m) = 2 - \pi(G) = 2 - g$ and $2\pi(F_\alpha^\beta) = 2\pi(E, H) = \pi(\rho_\gamma) = \pi(m) - 3$, (E and H are the electric and magnetic field strengths, ρ_γ is the energy density, e^2/hc is a pure number and both h/mc and GM/c^2 have the dimensions of a length), equations (4) become treating coordinates as dimensionless,

$$\frac{1}{\sqrt{g_*}} \left[\sqrt{g_*} F_*^{\mu\nu} \, \Omega_*^{4+\pi} \right]_{,\nu} = J_*^{\mu} \, \Omega_*^{4+\pi} \tag{6a}$$

$$u_{,\nu}^{*\mu} u^{*\nu} + \Delta_{*}^{\mu\nu} \frac{\Omega_{,\nu}^{*}}{\Omega_{*}} = \frac{e}{m} u^{*\lambda} F_{*\lambda}^{\mu} \Omega_{*}^{\pi+3}$$
 (6b)

with $\Delta_{\mu\nu} \equiv u_{\mu}u_{\nu} - g_{\mu\nu}$ and $2\pi \equiv 2\pi(F^{\mu\nu}) = \pi(m) - 7$.

Clearly, while equation (6a) can be made SI by assuming $\pi(m) = -1$, equation (6b) cannot, for the Ω_* dependence in the Δ term cannot be made to disappear because there are no free parameters in $\Delta_{\mu\nu}$. Therefore the system (4) is not SI.

Let us now consider a gravitational clock (a planet and a star, for example) and let us consider the Einstein equations describing macroscopic gravity. From the previous analysis it follows that the lack of SI of equations (4) is due solely to the equations of motion which in the gravitational case are already contained in the Einstein field equations, which can therefore be expected to be not SI. This is indeed the case²: Einstein equations do not retain their original form under the scale transformations (1)–(2). Their lack of SI is why a gravitational clock is a well-defined quantity, whose period, given by Kelper's third law, reads (M is the total mass and J is the orbital angular momentum per unit mass)

$$P = \frac{2\pi J^3}{(GM)^2} \tag{7}$$

The above discussion shows that the electromagnetic and gravitational clocks are meaningful because the dynamical equations governing them are not SI.

The strong equivalence principle

To study the relationship of the two clocks, consider a physical phenomenon characterized by a proper length interval Δs , which we shall measure using electromagnetic and gravitational clocks, the results being Δs_a (atomic) and Δs_E (Einstein), respectively.

Because clocks are the manifestation of underlying forces and we do not yet possess a unified theory, we do not know a priori whether the ratio

$$\frac{\Delta s_{\rm E}}{\Delta s_{\rm a}} = \beta_{\rm a} \tag{8}$$

is constant. The lack of knowledge of the function β_a has so far been circumvented by adopting the strong equivalence principle^{3,4} (SEP) which assumes that

$$\beta_a = \text{constant} = 1$$
 (9)

implying that, for example, the value of the period of a planet should be independent of the clock used to measure it.

The SEP comprises two assumptions³: (1) that the weak equivalence principle (WEP) holds; and (2) that local gravitational and non-gravitational experiments are independent of where and when in the Universe they are performed. The requirement (9) refers to 'when in the Universe', since, due to the high degree of homogeniety observed in the Universe, we assume that β_a is only time dependent. Furthermore one experiment is not sufficient to test the SEP, at least two experiments are needed at two different times, because β_a can be normalized to unity at any one time; what is physically relevant is $\dot{\beta}_a$.

Tentative evidence of a violation of SEP

Using 8,249 lunar occultation measurements⁵, lunar radar ranging data^{6,7}, and dynamical determinations of the lunar periods⁸⁻¹⁰, it has been suggested that at the present epoch $\dot{\beta}_{\rm a}/\beta_{\rm a} \simeq 10^{-11}~\rm yr^{-1}$. However, as tidal forces make the Earth-Moon system less than an ideal laboratory for our purposes, it would be more satsisfactory to use radar ranging data to the inner planets Mercury, Venus and Mars. Using the available results, an upper limit $|\beta_{\rm a}/\beta_{\rm a}| \leqslant 10^{-10}~\rm yr^{-1}$ was set¹¹.

We stress here one aspect of the theoretical analysis. It may seem natural to use the standard Einstein equations with the simple alteration $G \rightarrow G(t) = G_0 + \dot{G}_0 \Delta t + \cdots$, whenever G appears. However, from Einstein equations it follows quite generally that for an isolated system GM = constant (refs 12, 13), where M is the total mass. (For any local system, this constraint holds regardless of cosmological expansion³.) The violation of this constraint can lead to serious errors. For example, because the period and distance to a planet are given by $P \sim J^3/(GM)^2$, $R \sim J^2/(GM)$, GM = constant implies R = 0 and $\dot{P} = 0$ and not $2\dot{R}/R = \dot{P}/P = -2\dot{G}/G$, as usually stated. This

argument shows that a value of \dot{G}/G cannot be extracted from the standard Einstein equations where by construction G always appears multiplied by M, the product being required to satisfy the constraint GM = constant.

For these reasons, we (in collaboration with R. Helling and P. J. Adams of JPL) have enlarged the system of dynamical equations (originally used by R. Helling) to make them compatible with a possible violation of the SEP. The Viking radar ranging data to Mars are now being analysed. The best fit solution will hopefully provide a reliable value for β_a .

Purpose and basic assumptions

Let us construct a theoretical framework that allows for an SEP violation in the form of a non-constant β_a . This allows for the presence of two fundamental systems of units in nature, which is necessary to explore consistently the implications of an SEP violation as well as to provide relations which can be subjected to observational test.

Gravitational or dynamical units (EU, where E stands for Einstein), are the units in which Einstein equations remain unchanged. These field equations contain the equations of motion that yield the clock equation (7), which is therefore taken to give the gravitational or dynamical unit of time (also called ephemeris time). In EU, G_E = constant by definition and so the total mass is also constant, since $G_E M_E$ is constant. In addition, from $T_{E,\nu}^{\mu\nu} = 0$ applied to a pressureless fluid, we find that the rest mass is also constant. Therefore, in general

$$G_{\rm E} = {\rm constant}, \qquad M_{\rm E} = {\rm constant}$$
 (10)

where M is either total or (macroscopic) rest masses. As the particle number N will be shown not to be constant, equation (10) does not mean that microscopic masses m_E are constant in EU. Other atomic quantities such as e and h, are also in principle not constant in EU.

Atomic units (subscript a) are the units in which the dynamical behaviour of an electromagnetic clock is governed by equation (4), which in turn implies that equation (5) is taken to be the atomic unit of time. Furthermore, in AU we have

$$e_a = \text{constant}, \quad m_a = \text{constant}, \quad h_a = \text{constant}$$
 (11)

The first two terms are the analogue of (10) for microphysics. (Actually, terms in equation (11) are contained in equations (4).) In analogy with what we said earlier, the second term of equation (11) does not imply that macroscopic masses M_a are constant in AU. In fact, they are not (see equation (25)); G_a is also not constant (see equation (18)).

Let us now consider the basic problem of determining the relation of the two 'preferred' systems of units. We introduce a language that describes any physical equation in a general system of units of which the two 'preferred' systems are special cases.

Physics in general units

Let us reconsider equation (1) and transform L_* to L_{**} ,

$$L_* \to L_{**} = \Omega^{-1}(x)L_* = (\Omega_*\Omega)^{-1}L \equiv \Omega_{**}^{-1}L$$

The quantity Ω_* has therefore power -1, as from equation (3), where Λ^* , Λ and Ω_* are replaced by Ω_{**} , Ω_* and Ω , respectively. Therefore, any quantity of the form $\Lambda^*\Omega_*^{\pi^{(\Lambda)}}$ has zero power under subsequent scale transformations:

$$\Lambda^*\Omega_*^{\pi(\Lambda)} = \Lambda^{**}\Omega_{**}^{\pi(\Lambda)}$$

As an example, we perform a further transformation of equation (6) to a g_{**} , F_{**} , J_{**} system. The final result can easily be seen to be of the same form as equation (6), with only double starred quantities in it. Therefore, equation (6) can be said to be written in general units.

Let us now define a fiducial system of units by $\Omega_* = 1$, and a general system of units by $\Omega_* = \beta$. Here, as in previous work¹⁴,

we choose EU as the fiducial system ($\beta_{\rm EU}=1$), so that to be consistent with equation (8), the AU system is defined by $\beta_{\rm AU}=\beta_{\rm a}$. Note that while β , defining a general system of units, has power -1, $\beta_{\rm a}$ is of power zero, because $\beta_{\rm a}=\beta_{\rm AU}/\beta_{\rm EU}$ is the same in all systems of units. Clearly the use of general units does not introduce any new physics.

The action

To deal with the problem of constructing the two clocks, we propose an action in general units, which as such must be of zero power,

$$I = \int \mu \beta^{2-g} ds + \frac{1}{16\pi} \int \beta^{2-g} F_{\alpha\gamma} F^{\alpha\gamma} \sqrt{g} dx^4$$

$$+ \int \beta^{2-g} e A_{\nu} u^{\nu} ds$$
(12)

where μ represents masses in general (microscopic or/and macroscopic) and where the relation between $F_{\mu\nu}\beta^{1-g/2}$ and $A_{\alpha}\beta^{1-g/2}$ is the usual one. It is easy to check that the power of I is zero. Because the dimensions of I are [M][L], the β^{2-g} factors are required for $\pi(I)=0$. The matter part of equation (12) is different from that proposed by Dirac¹⁵ which is a particular case of equation (12) if $\mu\beta^{1-g}=$ constant. In AU, and for microscopic masses, this implies g=1, because of equation (11). However, g=1 will be shown not to allow the two clocks to run at different rates. The relaxing of the restriction $\mu\beta^{1-g}=$ constant is why we can construct two clocks that run at different rates.

Macroscopic gravitational clock

Consider the periodic motion of a planet in the gravitational field of a star. From the first term in equation (12), we derive the following equations of motion in general units,

$$u_{:\gamma}^{\alpha}u^{\gamma} + \frac{(\mu\beta^{2-g}),\gamma}{(\mu\beta^{2-g})}\Delta^{\alpha\gamma} = 0$$
 (13)

where the metric $g_{\mu\nu}$ due to the star is given in general units by the Schwarschild metric times β^{-2} . As we are dealing with a macroscopic object, then

$$\mu = M$$
, $M_E = \beta^{1-g}M = \text{constant}$ (14)

where the second relation is the general law for mass transformation from Einstein units to general units, following from equation (3) with $\Lambda = M_E$, $\Lambda^* = M$, $\Omega_* = \beta$, $\pi(m) = 1 - g$. The last equality in equation (14) follows from equation (10). Equation (13), with equation (14), specializes to

EU:
$$u^{\alpha}_{;\gamma}u^{\gamma}=0;$$
 AU: $u^{\alpha}_{;\gamma}u^{\gamma}+\frac{\beta_{a,\gamma}}{\beta_a}\Delta^{\alpha\gamma}=0$ (15)

The solutions for the period P can be easily worked out. The results are

EU:
$$P_{\rm E} = \frac{2\pi J_{\rm E}^3}{(G_{\rm E}M_{\rm E})^2} = \text{constant};$$

AU: $P_{\rm a} = \beta_{\rm a}^{-1} P_{\rm E}$ (16)

Electromagnetic clock

The motion of an electron in the field of a proton $F^{\lambda\nu}$, is governed by the following two equations, derivable from equation (12)

$$(\sqrt{g}F^{\lambda\nu}\beta^{1-g/2})_{,\nu} = 4\pi \int e\beta^{1-g/2} \delta^4(x^\alpha - z^\alpha) dz^\lambda \equiv J^\lambda$$
 (17a)

$$u_{;\nu}^{\alpha}u^{\nu} + \frac{(\mu\beta^{2-g})_{,\nu}}{(\mu\beta^{2-g})}\Delta^{\alpha\nu} = \frac{e}{\mu}u^{\nu}F_{\nu}^{\alpha}$$
 (17b)

In equation (17b) we used $e\beta^{1-g/2}$ = constant, a constraint derivable from equation (17a) using the antisymmetry of $F_{\mu\nu}$. Let

us now specify equation (17) to AU and EU. In AU we require equation (17) to coincide with equation (4). In AU, $\beta = \beta_a$, and for a microscopic mass $\mu = m = m_a = \text{constant}$. The requirement can therefore be fulfilled only if

$$g = 2$$
, $\pi(m) = -1$, $G_a \beta_a^2 = \text{constant}$ (18)

To derive the last term of equation (18) we have used equation (3) with $\Lambda = G_E$, $\Lambda^* = G_a$, $\Omega_* = \beta_a$, as well as equation (10).

The corresponding solution for the period p_a in a local lorentzian coordinate frame is now given by equation (5), with the subscript a attached to all the quantities. Let us now consider EU, where

$$\beta = 1, \qquad \mu \equiv m_{\rm E} = m_{\rm a} \beta_{\rm a}^{\pi(m)},$$

$$e^2 = e_{\rm E}^2 = e_{\rm a}^2 \beta_{\rm a}^{1+\pi(m)}$$
(19)

where we have again used equation (3). Because g = 2, equation (17a) retains the same form as in AU, whereas equation (17b) becomes

EU:
$$u^{\alpha}_{;\nu}u^{\nu} - \frac{\beta_{a,\nu}}{\beta_a}\Delta^{\alpha\nu} = \frac{e_a}{m_a}\beta_a u^{\nu}F^{\alpha}_{\nu}$$
 (20)

Using a local lorentzian coordinate frame, the solution for the period $p_{\rm E}$ is found to be

$$p_{\rm E} = \beta_{\rm a} p_{\rm a}$$
, $(p_{\rm a} = {\rm constant, equation 5})$ (21)

To achieve the desired result we had to fix a gauge: a relation between β_a and G_a , equation (18). This is a welcome feature because until now, we had to consider g as a free parameter ^{16,17}. This no longer the case, as the theory now demands equation (18). Note that such a gauge was previously suggested in connection with the 3K black-body radiation ¹⁸.

We have proposed a lagrangian whose solution for the periods of gravitational (P) and atomic (p) clocks are

$$P_{\rm E} = \beta_{\rm a} P_{\rm a}$$
, $p_{\rm E} = \beta_{\rm a} p_{\rm a}$, $P_{\rm E}$, $p_{\rm a} = {\rm constant}$ (22)

or

$$\frac{p_a}{P_a} = \frac{p_E}{P_E} \sim \beta_a \tag{23}$$

namely: in either atomic or gravitational units, the ratio of the periods of the two clocks is not constant, provided β_a is not constant. We have therefore proved that, provided g=2, a framework exists which allows the two clocks to run at different rates.

We must stress that the extension of equation (17a) to a charged fluid must be written as $F^{\mu\nu}$; $_{\nu} = \tilde{J}^{\mu}$, where $\tilde{J}^{\mu} = enu^{\mu}f$, f being an undetermined function of β_a . Due to the antisymmetry of $F^{\mu\nu}$, it follows that \tilde{J}^{μ} ; $_{\mu} = 0$, which implies eNf = constant. Because for g = 2, e is constant in any units, equation (19); it then follows that $f \sim N^{-1}$. The Coulomb force now becomes $e^2N^2f^2/r^2$. The analogous gravitational force is GM^2/r^2 , with $GM^2 = G_EM_E^2 = \text{constant}$, a result valid for g = 2. The correspondence between macroscopic Coulomb's and Newton's laws is therefore preserved.

Weak equivalence principle

In achieving the result (23), the central part was played by the action (12) and the equations of motion ensuing from it. Since equation (13) is in general units, using g = 2, the fact that $m\beta^{1-g} = m_E = m_a\beta_a^{1-g} \sim \beta_a^{-1}$, and equation (14), we obtain

Microscopic bodies:
$$u^{\alpha}_{;\nu}u^{\nu} + \frac{\beta_{,\nu}}{\beta}\Delta^{\alpha\nu} = \frac{\beta_{a,\nu}}{\beta_{\alpha}}\Delta^{\alpha\nu}$$
 (24*a*)

Macroscopic bodies:
$$u^{\alpha}_{,\nu}u^{\nu} + \frac{\beta_{,\nu}}{\beta}\Delta^{\alpha\nu} = 0$$
 (24b)

which indicate that the two types of bodies do not follow the

same type of trajectories. Equations (24) are still in general

From the operational point of view, we are only interested in AU, so we limit our considerations to them. Equations (24) tell us that in AU, microscopic masses follow geodesics while macroscopic masses do not. In either case, however, masses do not enter the equations and the WEP is separately satisfied, in the sense that all macroscopic objects follow the same path as do all microscopic ones. The results of the Eotvos-Dicke-Braginskii experiments^{3,19}, showing that two (macroscopic) bars of Al and Au (or Al and Pt) follow the same path, are therefore in full agreement with equations (24), as the extra 'force' represented by β_a , is independent of the mass and it affects both bars equally. Thus, its effect cancels out in this type of

To test equations (24) one should follow in time the trajectories of an atom and of a planet, which is the procedure in the radar ranging experiments. In fact, one may think of atomic and gravitational clocks (the Earth-Moon system), as two 'objects' moving in space-time following two given trajectories. If, as time evolves, the two systems follow different types of trajectories, charting the time evolution of the macroscopic object with the reference provided by the microscopic object cannot yield constant results if the ratio of the proper lengths spanned by the two objects is not constant in time. Therefore equations (24) are an alternative way of interpreting the lunar and planetary data that stresses the difference in the two trajectories rather than the difference of the two clocks. These two ways of interpreting the data are equivalent, although the second one is the one almost exclusively referred to in this context.

Particle number non-conservation

The fact that only g = 2 is allowed has important consequences. In fact, since m_a and M_E are constant, it follows that (using equation (3) between AU and EU)

$$m_{\rm E} \sim \beta_{\rm a}^{1-g}, \qquad M_{\rm a} \sim \beta_{\rm a}^{g-1}, \qquad N \sim \beta_{\rm a}^{g-1}$$
 (25)

implying that N is no longer constant. To have a conserved N, we have to choose either β_a = constant, in which case the SEP is automatically satisfied or g = 1, which would also lead us to an SEP conserving framework. In fact, for g = 1 the left-hand side of equation (15) governing the macroscopic gravitational clock in AU would be identical to that of equation (17b) governing a microscopic electromagnetic clock in AU, thus leading to no difference between the two periods P_a and p_a , thus returning to the SEP. (The right-hand side of (17b) does not affect this statement because, due to spherical symmetry, it does not affect the angular momentum conservation law).

Equation (25) is the most important consequence of the SEP violation framework as it indicates that a violation of the SEP is intimately related to a violation of the particle number conservation law.

Gravitational constant

It is often stated that if atomic and gravitational clocks are different, the gravitational constant G must vary with atomic time. While the statement is not incorrect, it may give the impression that it adds some new fact. This is not the case. In fact, neither in the gravitational action of ref. (14) nor in the one presented here, is there an independent function G. One calls G the combination $G_E \beta^{-g} = G$, $G_E = \text{constant}$. But one does not introduce new physics, one simply lumps together a function β , a parameter g, and a constant G_E . That the physics is contained in β_a and not in G_a , is evident from the fact that the experiments on the Moon and the inner planets, yield directly β_a and not G_a , which is derived quantity, equation (18).

Cosmological meaning of β_a

The framework presented here while permitting the examination of the implications of an SEP violation, does not explain the physical mechanism behind it. In fact, β_a is treated here as an external quantity, much as viscosity is treated in classical fluid mechanics, where it enters as an external parameter whose evaluation requires a microscopic kinetic theory.

Although we do not offer a dynamics for β_a , it is important to stress that a dynamics of β_a can be either of a local or global nature. In the first case, β_a is regarded as a space-time field described by an action to be added to the total action; this would entail a coupling of β_a to local matter, with the result that even in EU, macroscopic gravity would no longer be described by standard Einstein equations, thus departing completely from our basic assumptions. A local approach was adopted by Brans and Dicke (BD). As several studies have indicated^{20,21}, Solar System experiments constrain, within the BD approach, the variability of β_a to some orders of magnitude below the value quoted previously. As there is no reason why we should arbitrarily restrict β_a to such low values, we find the local approach inadequate.

The value of β_a implying $\beta_a/\beta_a \sim H_0$ suggests that β_a is related to the structure of the Universe and that its dynamics is likely to be governed by topological rather than local space-time considerations. The SEP violation represents therefore a cosmological influence on local physics, in accord with Mach's principle. In contrast, accepting the SEP as an exact law of physics is equivalent to assuming that local physics is independent of the rest of the Universe.

Recent work on nucleosynthesis²² has indicated that, as expected, an SEP violation with a time scale of the order of the Hubble time cannot be extrapolated back to the radiation dominated era. Furthermore a dynamics for photons can be constructed²² independently of β_a : in particular, a very general argument has been found indicating that the photon number N_{s} , contrary to the particle number N_{s} , equation (25), is adiabatically conserved for any value of the parameter g. (The photon treatment presented in (ref. 16) is therefore valid only if g = 1).

The two previous results suggest that an SEP violation, if it exists, began to manifest itself only after the Universe entered the matter dominated era, before which β_a may have been constant.

Conclusions

The most important results of the present analysis are:

- Einstein field equations retain their standard form only in EU. In AU, they depend on β_a and their form is given by equation (2.34) of ref. 14.
- The trajectory of a macroscopic (many body) object is a geodesic in EU; in AU, β_a factors enter. The results are given in equation (24b).
- The trajectory of a microscopic (one body) object is a geodesic in AU; in EU, β_a factors enter, equation (24a).
- While in AU the description of a microscopic one body dynamics is unchanged, (this holds true even at the level of the Schrödinger equation), the description of a many-body situation is affected by β_a . In fact, the particle number $N \sim \beta_a$, equation (25). This in turn implies that macroscopic masses are such that $M_a \sim \beta_a$, $M_E \sim$ constant, Microscopic masses are such that $m_a \sim \text{constant}$, $m_E \sim \beta_a^{-1}$. Finally, the gravitational coupling G is such that $G_E = \text{constant}$, $G_a \sim \beta_a^-$

We thank Drs P. J. Adams, J. Anderson and J. Lodenquai for constructive criticism, and Ms Doris Smith for typing the manuscript.

Protein dynamics investigated by the neutron diffraction-hydrogen exchange technique

A. A. Kossiakoff

Department of Biology, Brookhaven National Laboratory, Upton, New York 11973, USA

A new approach, using neutron diffraction and the hydrogen exchange (H/D) technique, has been used to study the extent and nature of the inherent conformational fluctuations in the protein, trypsin. The observed pattern of exchange was used to investigate systematic relationships between exchangeable sites and structural and chemical properties of the molecule. Results of this analysis indicate that hydrogen-bonding structure is the dominant factor governing rates of exchange. The model of conformational mobility which best explains the experimental findings involves a localized disruption of the secondary structure within different regions of the protein molecule, each limited in extent to the breaking of a small number of hydrogen bonds.

STRUCTURAL and chemical investigations have clearly demonstrated that, despite their high degree of hydrogen and hydrophobic bonding, proteins are far from rigid matrices of atoms and have certain component segments which exhibit considerable dynamic mobility¹⁻⁵. Because of their fundamental importance to the understanding of biological processes⁶⁻⁸ the dynamical properties of proteins have recently been the subject of intense study by a variety of methods. However, important issues remain concerning the effects of protein folding on the extent and nature of its dynamical motions.

I report here a study of the mobility characteristics of trypsin, a 223 amino acid protein, by coupling the hydrogen exchange (H/D) technique with neutron diffraction. Since its introduction by Linderstrom-Lang and his colleagues 9,10 , the H/D exchange method has been widely recognized to have great potential as a probe for protein conformational change (for detailed discussions of the potential applications of the H/D method to evaluating protein dynamics see refs 2, 11-14). H/D exchange has major advantages over other labelling techniques in that a deuteron has a negligible space requirement and has chemical properties nearly equivalent to those of the proton it replaces in the structure. Further, potentially labile sites are distributed throughout the molecule and therefore probe the dynamical properties of the whole structure.

Kinetic studies have shown that H to D exchange rates of peptide NH groups in a protein can differ by as much as 10 decades¹². It has been generally supposed that the groups which exchange at rapid rates similar to those characteristic of small molecules are those located on the surface of the protein and hence in direct contact with the solvent. Conversely, the groups which exchange much more slowly are assumed to be located in the interior of the protein and involved in internal hydrogen

It is generally accepted that in the conditions of this experiment (pH 7), the exchange reaction is catalysed by the presence of hydroxyl ion. However, little is known about other relationships between the exchange chemistry and the dynamical properties of proteins. For instance, the size of the solvent unit required to facilitate the exchange process is an open question, a situation which has led to the postulation of two distinct stereochemical models for exchange. One model, which will be referred to as the cooperative or local unfolding mechanism, is described by a transient, cooperative unfolding of a segment of secondary structure 11-13. Access to the exchangeable protons is assumed to be accomplished by the extrusion of the chain into the bulk solvent where the exchange reaction can proceed by normal water chemistry. In the second model, the penetration mechanism, it is assumed that the exchange reaction takes place, shielded completely from the bulk solvent, within the tightly packed interior of the protein. It is proposed that the necessary solvent molecules can be diffused through the protein to the interior sites via pathways opened by local atomic fluctuations¹⁴ or by mobile defects in the protein packing¹⁵.

A variation of local unfolding is introduced here and termed 'regional melting'. It differs from the mechanism described above in that exchange does not require the chain to be extruded into the bulk solvent. In this variant, the reconformation process is limited to the cooperative breaking of several hydrogen bonds, resulting in the formation of a solvent-filled cleft in the protein surface. The exchange is assumed to take place within the cleft if the cleft is sufficiently large to permit the solvent molecules to arrange themselves in a stereochemically productive orientation with respect to the exchange site. Although the solvent molecules within the clefts cannot be considered to have chemical properties identical to the bulk phase, they are assumed to be contiguous to the bulk solvent.

Unfortunately, previous H/D exchange experiments have been unable to relate exchange rates with specific groups or even regions of polypeptide chain, thus limiting the usefulness of exchange methods in elucidating the factors responsible for protein conformational mobility, and the mechanism of the exchange reaction.

Recently, the application of NMR spectroscopy ¹⁶⁻¹⁸ and chemical analysis ^{13,19,20} to H/D exchange has begun to provide data relating exchange rates to structural features. The present article reports on the application of neutron diffraction to this problem. Two factors make this technique particularly suitable for providing a direct and quantitative approach to the measurement of H/D exchange rates of specific sites. First, because it is a crystallographic technique, the precise location of each labile site in the well-ordered segments of the protein is known and can be examined directly in a neutron Fourier map. Second, because the amplitudes of hydrogen and deuterium scattering are of opposite signs (Fig. 1), the process of assigning a labile site as having either H or D character is quite a straightforward task, provided that the structure of the protein has been highly refined, as is the case for trypsin.

As will be seen from subsequent discussion, the goal of this study is not simply to obtain dynamical information about the trypsin molecule *per se*, but to use trypsin's structural units, its β -sheet and α -helix regions, its turns and loops, to investigate through H/D exchange how each type of unit reacts to the conformational mobility modes of the protein. Correlations between the exchangeability of a potentially labile site and four principal factors are examined: (1) the degree of local hydrogen bonding structure around the site, (2) its distance to the solvent, (3) the hydrophobic or hydrophilic character of adjacent side chains and (4) its observed vibrational motion (temperature factor).

Crystalline proteins as models for dynamic studies

It could be objected that, since diffraction methods are limited to the study of crystalline proteins, they might be expected to yield different results from studies of proteins in solution. The use of a crystalline system to model a dynamic phenomenon like conformational mobility is valid because a protein molecule in a crystal is highly solvated and has an environment very similar to that in solution²¹⁻²³. Thus, crystallographic studies have shown that a protein crystal can best be described as an ordered and open array of molecules held together by a relatively small number of intermolecular contact points. The interstitial region between molecules generally makes up about one-half of the total crystal volume24, and is comprised of a network of continuous channels filled with solvent having properties analogous to bulk water ^{23,25,26}. Because of the extent of unoccupied volume in the crystal, ions and substrates can readily diffuse through the solvent channels to interact with the protein. Analysis of the extent of the solvent network in the trypsin crystal (≈46% solvent by volume) revealed several channels having cavities as large as 18 Å across.

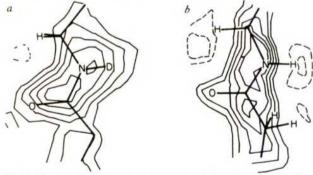

Fig. 1 Sections of a neutron density map taken in the plane of the peptide group. a, Fully exchanged peptide group, scattering length of $D=+6.7\times 10^{-13}$ cm; b, unexchanged peptide group, $H=-3.8\times 10^{-13}$ cm. In cases where partial exchange has taken place, the expected density at the H/D site is close to zero. This is because with H and D having scattering amplitudes of opposite sign, the composite scattering density tends to cancel in the Fourier summation. In the refinement, H/D sites were assigned a temperature factor based on that of the amide nitrogen, and occupancy factors alone were refined. In those regions of the structure with a high degree of thermal motion or local disorder, H/D ratios were not considered reliable and the affected residues are identified in Fig. 2 legend.

Given this structure, the protein molecules themselves would be expected to exhibit many of the chemical traits found in their fully solvated state. Particularly relevant to the present study are several investigations comparing the H/D exchange kinetics between crystalline and solvated protein systems^{27–30}. The exchange properties of solution and crystal systems were found to be very similar, implying that accurate exchange information can indeed be obtained from a crystalline protein system.

To determine whether or not lattice packing forces at contact areas between adjacent molecules in the crystal produced a measurable degree of inhibition of the exchange reaction, the peptides involved in the principal contact zones were identified and their degrees of exchange examined. All but one of the sites were found to be completely exchanged (the lack of exchange at this site is probably due to its being in a β -sheet structure and not a result of the contact), which demonstrated that such inhibition as might be encountered in the molecular contact regions was not significant for the reaction time of this experiment. However, this analysis does not exclude the possibility that some of the more extensive modes of motion might in some ways be impeded by the lattice forces.

Experimental procedures

A 5-mm3 crystal of monoisopropylphosphoryl (MIP) trypsin was soaked in a D₂O solution at pH 7 and 20 °C for ~1 yr before data collection was begun. (The MIP group is a small covalently bound inhibitor which does not affect the tertiary structure of the protein31.) Data to 1.8 Å resolution (14,500 reflections $> 3\sigma$) were collected on a two-dimensional positionsensitive detector system32 at the Brookhaven High Flux Beam Reactor. These data were processed by a method developed in this laboratory to deal specifically with the problems inherent in obtaining accurate intensity measurements from the weak neutron diffraction of protein crystals33. The initial phasing model was calculated by applying the appropriate neutron scattering lengths to the refined trypsin X-ray coordinates of Chambers and Stroud³⁴. Refinement of the structure was carried out by the restrained difference Fourier technique, which involves the determination of proper atomic shifts by the curvature-gradient method and then the re-idealization of the structural parameters by an energy minimization routine. Details of these experimental procedures are reported elsewhere³¹. The current trypsin model is highly restrained to ideal bond lengths and angles (r.m.s. error in bond lengths < 0.014 Å, bond angles $< 1.4^{\circ}$). After eight cycles of refinement the R factor is 19.2%.

The peaks produced in a neutron density map by sites having intermediate exchange ratios (between 15% D-85% H and 60% D-40% H) were found to give densities of a magnitude comparable with the general noise features of the trypsin map; therefore, prediction of relative exchange ratios between sites within this range cannot be made with statistical confidence. Accordingly, it is appropriate to subdivide the exchange ratios into three major categories: (1) unexchanged (0-15% D), (2) partially exchanged (15-60% D) and (3) fully exchanged (60-100% D). Limiting the number of categories in this manner will retain the informational content of the H/D data while guarding against over-interpretation of the relevance of small changes in exchange ratio.

Patterns of exchange

The degree of exchange of the amide hydrogens, as determined from the neutron diffraction analysis, is represented schematically in Fig. 2. Three-dimensional views of the main-chain atoms of the molecule represented in space filling and ball and stick form are shown in Fig. 3, which illustrates the exchange pattern as a function of the structure and folding of the protein. Sidechain groups were omitted to permit an unencumbered view of the intramolecular main-chain hydrogen bonding.

In summary, of the 215 exchangeable amide groups, 68% were found to be fully exchanged, 8% partially exchanged and 24% unexchanged. This corresponds to the cumulative result

of the exchange process throughout the entire span of the D_2O soaking of the crystal, because once a D replaces an H in the structure, any further exchange at the site is between Ds because of the low concentration of hydrogens in the soaking solution.

Although this experiment only distinguishes sites which exchange fast or slowly relative to the fixed time of reaction (1 yr at pH 7, 20 °C), the relatively low fraction of partially exchanged sites indicates a very substantial difference between the degree of protection provided by structural features of the protein to the unexchanged sites and that afforded the exchanged sites.

Inspection of Fig. 2 reveals that the unexchanged sites form a distinctive pattern whose most prominent feature is the clustering of unexchanged sites in regions corresponding to the B-sheet structures of the protein. The interior core of trypsin consists of two such structures, called '\(\beta\)-barrels', each consisting of six antiparallel strands laced together by a network of hydrogen bonds. In fact, 45 of 52 unexchanged hydrogens are found in the β -sheet structures. Closer examination of these regions shows that only 11 of the peptide groups involved in B-sheet hydrogen bonding are completely exchanged, and all of these are located at edges of sheet structures. Modelling studies performed by Salemme³⁵ show that extended β -sheet structures can withstand substantial deformation without disrupting their hydrogen bonding network. The present findings are consistent with this observation. Note, however, that the structural integrity of a β -sheet unit is not wholly a hydrogenbonding phenomenon, but also involves hydrophobic forces.

Significant data regarding the accessibility of sites within the tightly bonded β -sheet core come from the exchange behaviour of the hydroxyl group of the Ser 54 side chain. As illustrated in Fig. 4, which shows a segment of buried β -sheet (residues 43–45, 53–56), the Ser OH group forms hydrogen bonds to 43 O and 55 NH. Thus, it is embedded in the main β -sheet network and consequently has the same degree of protection as its neighbouring peptide groups. This hydroxyl group is found to be almost fully exchanged, while the amide proton of residue 55 is unexchanged, as are its neighbours.

The exchange of the OH group, which is considerably more reactive than peptide NH groups 11,12 , demonstrates that conformational fluctuations large enough to expose the β -sheet region to attack by the solvent do occur, but with insufficient probability for the slower peptide exchange to progress appreciably within the time frame of the experiment.

In addition to considering structural and bonding effects, it is important to examine and discuss several other parameters which might be expected to affect the exchange process, notably solvent accessibility, the chemical nature of side chains, and observed vibrational motion.

Effect of solvent proximity on rates of exchange

The degree of exchange of sites located near the surface of the protein molecule would generally be expected to be greater than that of sites buried in the interior. To test the magnitude of this effect, the distance of each peptide proton to the nearest bulk solvent interface was computed. Figure 5a plots this distance against the degree of exchange. The average distance between peptide sites and the protein surface was found to be $3.8 \, \text{Å}$.

As might be anticipated, >90% of unexchanged sites were located 4 Å or more from the surface. However, as many as 27% of the fully exchanged sites were also located 4 Å or deeper. Because access to such sites would presumably require rather substantial conformational fluctuations, the 20 exchanged sites located 5 Å or deeper were examined to determine whether they were near one of the small clusters of water bound in cavities inside the molecule. Nine of these sites were, in fact, located adjacent to one of several interior water molecules. Thus, if the distance to the solvent interface is redefined to include interior water cavities, the average distance

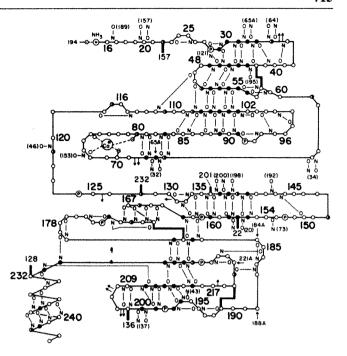

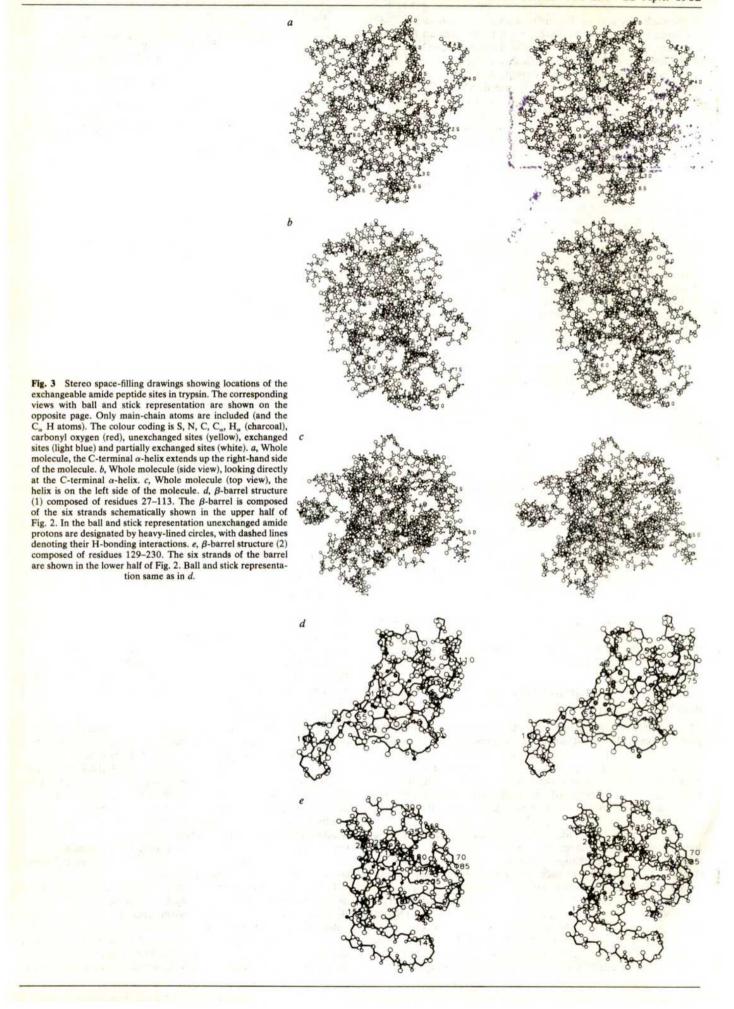

Fig. 2 Schematic representation of H/D exchange at each amide peptide site in the trypsin molecule. Key: ○, full exchange; ④, partial exchange; ♠, unexchanged; ⊕, proline; ↓, sequence insertions; ↑, deletions (based on the chymotrypsinogen numbering scheme); ⊝, carboxylate side chains. Peptide NH and carbonyl O atoms are shown when H-bonded. Disulphide bridges are indicated by broad lines. Because of the effects of thermal motion or local disorder, the H/D exchange information for residues 60–62, 110–111 and 147–150 is not reliable. (Figure design adapted form Birktoft and Blow⁴⁶.)

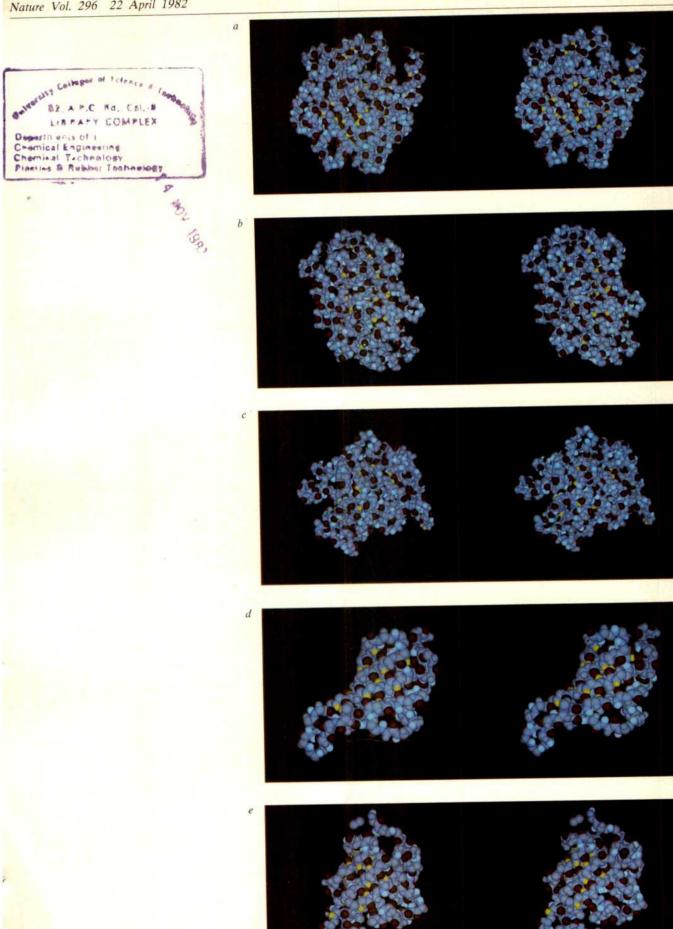

of these sites from solvent decreases by 2.65 Å (only two sites remain as far as 5 Å from solvent) and the overall average distance of all peptide protons in the molecules from solvent decreases by 1.1 Å to 2.7 Å.

Recent investigations have shown that trypsin is not a unique protein in having a significant number of interior water cavities (I. D. Kuntz, personal communication). The finding that the water molecules residing in the cavities are fully exchanged for D₂O suggests that free solvent exchange occurs between the bulk and interior solvent regions. Figure 6, which shows a low-resolution (5 Å) electron density model of trypsin, gives some idea of the extent of these cavities. Note that, because of the limited resolution of the data and the density contour level used in the construction of the model, the actual sizes of the cavities are exaggerated. Even so, the 5 Å density model still presents a very instructive picture regarding the extent of the cavity network in the trypsin molecule. (The entrances to the pockets holding the interior water molecules are marked in Fig. 6.) Further, a majority of the holes pictured in the 5 Å model were found to coincide with the location of the set of cavities determined from the refined 1.8 Å structure.

In several cases these water cavities are sealed off from direct contact with bulk solvent by only one or several side-chain interactions; the reorientation of the side chains to accommodate interior-bulk solvent contact would presumably be of relatively low energy compared with structural fluctuations which break main-chain hydrogen bonds. Hence, it is plausible that structural fluctuations of the groups surrounding these internal cavities might represent natural low-energy pathways for solvent access and 'regional melting'.

It was noted above that a strong correlation exists between non-exchanged peptides and hydrogen-bonding sites in the β -sheet structures. As the β -structures are located deeper within the protein (3.8 Å) than the remaining sections (2.3 Å), an effort was made to separate out the effects of structure and depth. The average depth of the 11 fully exchanged sites located in the β -sheet structures is 4.0 Å, which corresponds closely

to the average depth (3.8 Å) of the total β -sheet population and implies that distance to the solvent is not a primary factor in determining exchange characteristics of β -structures.

In the non- β -sheet sites, the 133 fully exchanged sites were located at an average distance of 2.1 Å from the solvent, while the 7 unexchanged sites were at 4.3 Å. This suggests that the depth effect may be a real one, but the number of unexchanged sites is too small to provide confidence in the result. Note that even after the interior water cavities are taken into account, many sites 3 and 4 Å from the solvent interface are fully exchanged. This would imply that the molecule has sufficient internal mobility to provide access to sites when they are not immobilized by secondary structures.

A graphic example of the dominant role of secondary structure on exchange characteristics is illustrated in Fig. 7, which shows a region of β -sheet containing an occluded water molecule. In the structure, a pair of hydrogen bonds is formed between peptides 215 and 227; the amide hydrogens are unexchanged in both peptide groups. There is a well-ordered water molecule perpendicular to the plane of the sheet which hydrogen bonds to both carbonyl oxygens and to Ser 190 O, (not shown). The clear implication is that an amide peptide group can participate with water (in this case D2O) in a hydrogen bond to the same acceptor ligand and yet remain unexchanged. (This is not an isolated case, since similar arrangements have been observed in five places in the trypsin molecule.) In the above instances there is clearly solvent access to peptide sites which nevertheless remain unexchanged, indicating that structural (bonding) effects dominate over the effect of solvent accessibility.

Neighbouring side-chain effects

It has been suggested that the different chemical characteristics of side chains might, by inductive effects³⁶ or by changing the

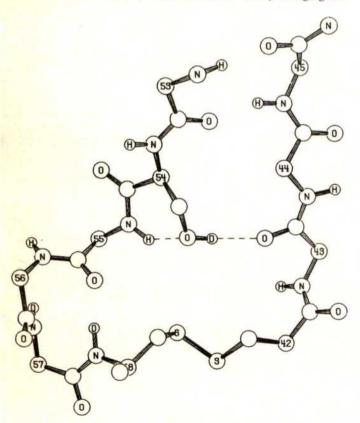

Fig. 4 Section of β -sheet structure residues 43–45 and 53–56 showing main-chain atoms (and the side chain of Ser 54). Because of a bulge in the sheet, the H-bond interaction between 43 O and 55 NH cannot be made directly. The bonding structure of the sheet is maintained (dashed lines) through the mediation of the side chain of Ser 54. The hydroxyl proton of the serine is almost fully exchanged for a D, yet the amide proton of Ala 55 to which the hydroxyl oxygen is H-bonded remains unexchanged.

local water chemistry ^{37–39} around the neighbouring peptide site, significantly affect the rate of H/D exchange. The importance of inductive effects was verified by Molday et al. ³⁶ who systematically evaluated the nearest-neighbour side-chain effects using small model peptides and derived a set of empirical rules which could predict rates of exchange in random order peptides from their amino acid sequence. Most of the hydrophobic and hydrophilic side-chain effects were found to span a 10-fold range. Other studies have shown that exchange in model polyamides is slowed by the presence of bulky apolar groups, even though the peptide nitrogen itself was not involved in hydrogen bonding ^{39–41}. In the light of these investigations, it is important to ascertain whether or not patterns of exchange in the trypsin molecule are also affected by the nature of the associated side chains.

The observed character of these near-neighbour effects³⁶ might suggest that the presence of a hydrophobic side chain would make the adjacent nitrogen more resistent to exchange. In trypsin, the groups alanine, leucine, isoleucine, methionine, phenylalanine and valine account for 65 of the 215 potentially exchangeable sites. Of these, 44% were found to be fully exchanged, 8% partially exchanged and 48% unexchanged. Of the hydrophilic groups—arginine, asparagine, aspartic acid, glutamine, glutamic acid, histidine and lysine—which account for 53 sites, 79% were exchanged, 8% partially exchanged and 13% unexchanged.

Comparison of above values with the average for the entire molecule (68% fully exchanged, 8% partially exchanged and 24% unexchanged) indicates a strong correlation between the degree of exchange and the polarity of the associated side chain. However, before concluding that this correlation is significant, it is necessary to determine whether this effect is independent of the structural correlation previously observed between β -sheet structures and exchange character.

There are 59 sites involved in the two six-stranded β -sheet structures. Of these, 29 are hydrophobic, while only 11 are hydrophilic. (Such hydrophobic/hydrophilic ratios are typical of β -structures of most globular proteins⁴² and it is generally assumed that the high concentration of hydrophobic groups contributes to the unusual stability of these structures.) These β -sheet sites account for all but seven unexchanged groups. Thus, when the members of the β -sheet structures are removed from the hydrophobic population, a large percentage of the remaining groups are fully exchanged (72% fully exchanged, 8% partially exchanged and only 20% unexchanged). Conversely, of the 11 hydrophilic groups which participate in β -sheet structures, 27% are fully exchanged, 9% partially exchanged and 64% unexchanged.

The above analysis suggests that in the conditions of the experiment (1 yr soaking), any effect of side-chain character which might either promote or inhibit exchange is dominated by the more powerful effects of structure and the hydrogen-bonding character of the sites.

Temperature factor correlations

Investigators have attempted to gain insight into the phenomenon of dynamic mobility by using temperature factor data from detailed X-ray analyses of several proteins 3.4.43. The attraction of this method is that it identifies specific groups in the protein structure whose locations show positional variation due to thermal motion. However, the method has several limitations. Protein dynamics as described by temperature factor correlations involve small atomic displacements (of the order of 0.5-1.5 Å), and thus represent as a class rather low-energy conformational fluctuations. Further, at the resolution level of normal protein structure analysis (that is, below atomic resolution), accurate individual temperature factor values (B factors) are difficult to obtain. Local trends of group B factors offer a considerably more reliable measure of motion and, therefore, during the refinement procedure, B factors are usually restrained in some fashion to be similar to those of their near neighbours.

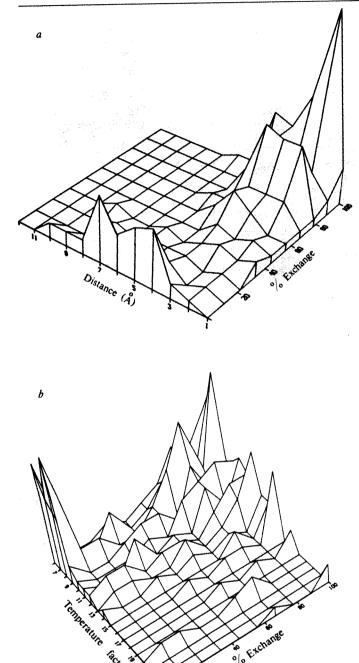

Fig. 5 a, Exchange ratios (0-100%D) of the peptide NH sites plotted as a function of their distance to the bulk solvent. Internal water cavities were not considered in the analysis. The molecular envelope was calculated using an atomic radius of 1.4 Å for all atom types including hydrogen. A radius of this size, when applied to hydrogen, overestimates the spatial volumes of most groups and therefore tends to extend the envelope outside the bounds of the molecule defined by the coordinates of the static structure. However, it was felt that in this type of analysis it was important to enlarge the molecular envelope slightly to take into account the small vibrational motions and positional disorder of the surface residues, effects which also increase slightly the molecular boundary. Thus, the resulting site to solvent distances are defined here to reflect a maximum distance, that is, a distance of 1 Å represents a true distance of 0-1 Å to solvent; a distance of 2 Å is 1-2 Å and so forth. Note that in most instances solvent proximity, as defined here (shortest distance to the solvent interface), would not be expected to correlate with solvent accessibility exactly because the low energy pathway by which solvent gains access to a site does not necessarily correspond to the same pathway which defines the shortest distance. b, Plot of exchange ratios of the peptide NH sites as a function of their experimentally determined temperature factors. Exchange categories are partitioned as follows: (1) unexchanged (0-15% D), (2) partially exchanged (15-60% D), (3) fully exchanged (60-100% D). Heights of the peaks correspond to the number of sites at each occupancy grouping. Highest peak in a (which is distance 2 Å and 100% D) represents 25 sites, in b a temperature factor of 8 at 0% D represents 10 sites.

Sternberg et al.³ attempted to use thermal factor parameters to describe correlated rigid body motilities of extensive segments of polypeptide chain, applying a sophisticated mathematical treatment to assess the modes of intramolecular motion (so called hinge-bending motions) between the two major globular lobes in lysozyme. From their analysis they conclude that temperature factor information offers only weak evidence for any hinge-bending motions. This suggests that if the coupled modes of movement between the two lobes exist in lysozyme they are structural fluctuations of the high-energy, short-lived type.

The conclusions of Sternberg et $al.^3$ are corroborated by the findings of the present neutron analysis. Figure 5b shows the correlation between individual amide peptide temperature factors and H/D exchange ratios. As expected, the unexchanged amide groups are distributed in a narrow range at low temperature factors, indicating that they are predominantly located in interior, highly structured regions of the protein. It is somewhat surprising, perhaps, to find that many of the fully exchanged sites are also distributed near the low end of the temperature factor scale. This suggests that they, too, are highly ordered, at least on a crystallographic time scale, but must become sufficiently exposed to solvent as a function of the general breathing modes of the protein to promote exchange.

Because many exchanged interior sites have B-factor values comparable with those of the unexchanged sites, I conclude that no distinct correlation exists between the potential exchange of an interior site and its observed thermal motion. This finding has an important implication with respect to the use of crystallographically determined temperature factors to describe protein motions. Although these parameters have been shown to be of value in identifying local dynamic trends involving small atomic displacements, they appear to contain no systematic information on the characteristics of the larger-scale breathing modes of this protein.

Concluding remarks

It has been reported that the variation in the rate of H/D exchange of peptide groups in a protein molecule ranges over as much as 10 decades¹². The conditions of the experiment reported here were apparently such as to exchange all except those sites which were especially well protected by the protein structure. Clearly, an important future study would involve a comparative analysis of a crystal soaked for a shorter time to identify those sites which exchange slowly on an absolute scale, but rapidly enough to be fully exchanged in the conditions used here.

In summary, it appears that essentially all the sites in which the peptide hydrogens are bonded directly to water molecules—either in the bulk solvent regions or in interior clusters—are fully exchanged. No significant inhibition of peptide exchange was apparent at molecular contact points in the crystal, at hydrophobic side chains or as a function of degree of vibrational motion of the site, except when any of these also corresponded to hydrogen-bonded structures. Further, most of the sites in which the peptide hydrogens are involved in isolated bonds to either side-chain groups or main-chain carbonyls are fully or partially exchanged. Finally, those sites in the β -sheet structures which are not only hydrogen bonded to main-chain carbonyls, but are also flanked by similarly bound peptides, are to a very large extent unexchanged.

In the two short segments of α -helix in the trypsin molecule, the peptides are almost wholly exchanged. The only fully unexchanged sites, Ile 238 and Ile 242, are located along the interface between the helix and two strands of β -sheet. The spatial relationship between these groups and the sheet can be seen in Fig. 3a. (As pictured, the helix is located on the right side of the molecule with the amide protons of 238 and 242 shown in yellow.) The finding that the exchange properties of the helix peptide nitrogens differ substantially (apparently depending on whether or not hydrophobic intramolecular contacts are made) indicates that such conformational fluctuations

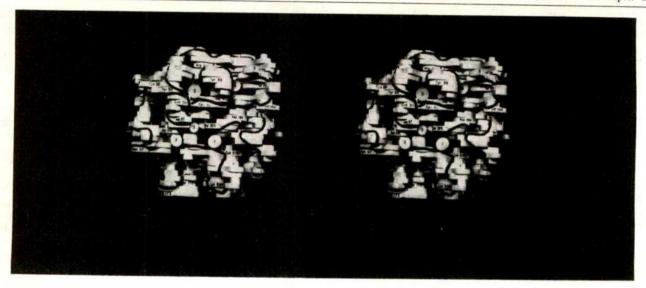

Fig. 6 5 Å density model of trypsin. Water cavity pockets are numbered. Cavity number 1 is the entrance to the substrate binding pocket.

as may be responsible for exposing the groups to solvent probably involve the breaking of hydrogen bonds only adjacent to the exchanged sites rather than the cooperative unfolding of the full helix unit. If such an unfolding process were to occur, it would be difficult to explain how these two particular sites remain unexchanged (especially in light of the fact that they both fit a distinctive pattern with respect to their packing against the β -sheet).

Figure 7 illustrated the important point that solvent accessibility alone is not a sufficient condition for exchange. The finding that rates of exchange are highly correlated to the structural features of the protein, especially hydrogen bonding, is consistent with the hypothesis that the segments of a protein molecule continually undergo local conformational fluctuations in which interior sites occasionally become aligned in chemically reactive orientations with solvent molecules. This mechanism predicts that the relative exchange rate constants would be dependent on the equilibrium concentrations of the unfolded species, which in turn would be a function of the energy required to overcome the local internal bonding of the folded structure. However, there is no evidence that extensive reconformation of the polypeptide chain is necessary to expose even the well buried exchanged sites. The finding that the exchangeable sites are partitioned almost exclusively into just two categories (fully exchanged and fully unexchanged, with relatively few sites being partially exchanged), implies that significantly different energies are required to overcome the internal bonding within the various domains in the molecule. Similar findings have been obtained through other experimental techniques 44,45.

The fact that full exchange occurs at regions of direct contact of adjacent molecules in the crystal, where gross motion is certainly minimized, indicates that outside the β -sheet structures relatively limited displacements of the structure suffice to provide the necessary access to enable exchange to proceed. This is also borne out by the complete exchange of internally occluded water molecules. Although it seems likely that solvent cavities provide natural pathways for access to some of the deeply buried sites in trypsin, the principal results of this experiment are inconsistent with a mechanism based on the premise that depth of burial of a site is a primary factor governing its rate of exchange. The most likely model to explain the observed exchange behaviour seems to be one involving localized conformational mobility, where the most probable fluctuations are those characterized by a degree of 'regional melting' usually limited in extent to the breaking of only a small number of hydrogen bonds. Further investigations aimed at resolving issues concerning the relationships of exchange chemistry to

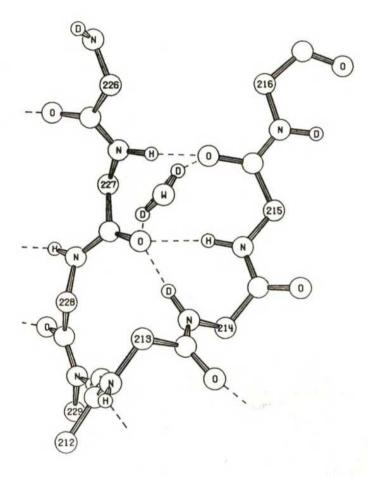

Fig. 7 Section of β -sheet showing the H-bond interaction between 227 NH-215 O, and 227 O-215 NH. An ordered D₂O molecule shares this H-bond, yet the peptide NH protons are unexchanged. The locations of the D atoms on the D₂O molecule were determined from the neutron density map, to indicate how the D₂O was oriented relative to the coordination ligands (215 O and 227 O). Note that the 214 amide is fully exchanged. Calculations indicate that the 214 and 215 amide protons are equally close to the solvent interface. Their respective hydrogen bond strengths are quite different. The 227 O-215 N hydrogen bond is classified as normal (2.9 Å), whereas the 227 O-214 N distance is quite long (3.5 Å), indicating a weak interaction.

protein dynamics should profit by the application of modelling studies using the exchange information reported here as a data

The formation of galactic haloes in the neutrino-adiabatic theory

Adrian L. Melott*

Center for Relativity Theory, The University of Texas at Austin, Texas 78712, USA

Recent evidence of a finite rest mass for the neutrino has led to a revival of the idea that these particles may provide the unseen but dynamically indicated matter on cosmological scales of galactic halo and larger size. In the early Universe, the free streaming of collisionless neutrinos is seen to damp out perturbations less than of the order of tens of Mpc long1 numerical simulation of the clustering of collisionless particles in a universe with this type of perturbation spectrum⁶ has led to the formulation of a cell structure with large voids. Many observations^{7,8} support the existence of such a structure on scales of tens of Mpc. However, collapse of perturbations of this size leads to velocities of the order of 1,000 km s⁻¹, and as the neutrinos presumably cannot cool, this seems to be too large for their inclusion in galactic haloes, which have much smaller velocity dispersions. Thus it has been suggested that neutrinos cannot cluster in galactic haloes without some means to 'save' smaller-scale perturbations^{3,4,9}. Furthermore, if neutrinos of mass ~30 eV form galactic haloes, the phase space density must be very close to the primordial one 10—and phase mixing is often associated with collapse. Although the average value of the velocity dispersion may be reduced if the perturbations are anisotropic11, a disparity still remains. I now present a numerical simulation which shows that if the initial perturbations are sufficiently anisotropic, the collapse of very large perturbations of collisionless particles leads to a condensation of particles with low velocity dispersion and high phase-space density, which may easily fragment.

A series of numerical simulations were initiated to study the collapse of large-scale perturbations of massive neutrinos. The technique used was the "cloud in cell" method¹², which accurately models collective effects while suppressing two-body effects (such as the large-angle gravitational scattering of one neutrino by another), which are not important for neutrino clustering. The gravitational potential was derived using a Fast Fourier Transform method, with periodic boundary conditions, in co-moving coordinates6. I began with a study of the planesymmetric case, an approximation to highly anisotropic collapse, because anisotropy may increase during collapse¹

A high-resolution one-dimensional simulation, to be published elsewhere 14, showed that the central region of the phase space (see Fig. 1) is dominated by a high phase-space density, low velocity dispersion condensation. A sinusoidal perturbation of 100 Mpc wavelength was chosen for the simulation so as to test the hypothesis severely. The 100 Mpc field was divided in successive simulations into 10², 10³ and 10⁴ grids, onto which were placed 10³, 10⁴ and 10⁴ particles respectively. Changing the resolution from slightly larger to much smaller than the condensation had no effect on the conclusion, apart from low-level noise introduced in the third simulation by the smaller number of clouds per cell. Imposition of even highly asymmetric initial perturbations resulted in an asymmetric condensation, with a small net momentum, but still with the crucial high phase-space density and low velocity dispersion.

For a sinusoidal initial perturbation of amplitude $\delta \rho / \rho \sim 10^{-3}$ at $z = 10^4$ and a wavelength of 100 Mpc, in a universe of Hubble constant 75 km s⁻¹ Mpc⁻¹ and Ω (density relative to critical density) of 1.07, about 12% of the (10⁴) particles were bound in the central Mpc, with velocities < 200 km s⁻¹. Furthermore, the condensation was found to have a phase-space density very close to that of the primordial distribution.

A two-dimensional code was developed, using a 100×100 grid field scaled to 1 Mpc per grid. This code was found to conserve energy to 1.7% or better (a considerable improvement over past calculations of this type⁶), depending on choice of time step; to reverse itself from a collapsed state to the uniform distribution; and to behave like an analytical solution for the

^{*} Present address: Department of Physics and Astronomy, University of Pittsburgh, Pittsburgh, Pennsylvania 15260, USA

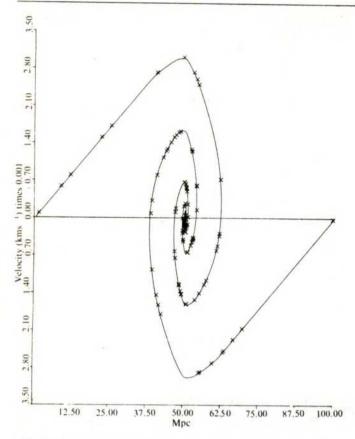

Fig. 1 A plot of the phase space of the one-dimensional simulation at Z=0. A solid line connects the particles, and a cross is drawn at the position of every one-hundredth test particle. Note the condensation of particles to the central Mpc.

case of uniform spherical symmetric perturbations. It contained two populations of particles: those given no initial velocity and a test population with thermal velocities appropriate to 30 eV neutrinos.

The result of collapse to Z=0 is seen in Fig. 2. A central slab is visible in the plot in which the darkness of a grid is proportional to its mass density. An $x-V_x$ projection of this result duplicates Fig. 1. The central region would be the predicted site of galaxy formation in the adiabatic theory, as the 'normal' matter undergoes collision and shocking. Somehow the collisionless neutrinos must cluster around these galaxies.

Figure 3 shows the result of assigning only 1% of the mass to 'protogalaxy grids' at Z=5, the moment of pancaking of the neutrinos. The pattern again is that of the distribution of test particles, which are strongly clumped around the protogalaxies. The same clumping appeared if the mass was slowly assigned to protogalaxies from Z=5 to 4. In this case, it was found that 7% of the test particles were bound within the protogalaxy grids and had velocities $<200 \,\mathrm{km \, s^{-1}}$. If the protogalaxies are chosen to be of smaller mass, distributed more evenly, the amount of material 'captured' increases because fewer particles acquire velocities greater than the $200 \,\mathrm{km \, s^{-1}}$ limit. Very small perturbations are sufficient to fragment the neutrino pancake.

Figures 2 and 3 are not to the same gray scale—black is adjusted to be the grid of highest density. The dark grids in Fig. 3 are of the same density as the local group, if it is bound.

Therefore sufficiently anisotropic perturbations will permit massive neutrinos to cluster in regions of low velocity dispersion, high mass density and high phase-space density. P. J. E. Peebles (personal communication) has pointed out that the central mass density of these regions must be much larger than the average shown here. My simulation cannot accurately model the dynamics inside a grid. It has been shown 13, however, that

a condensing protogalaxy can capture a significant number of neutrinos, resulting in a density enhancement in a central region, so that the neutrino density becomes comparable with the baryon density, which is demanded by flat galactic rotation curves.

Therefore the collapse of large-scale perturbations of collisionless particles results in a condensation of particles of low velocity dispersion and high phase-space density. This con-

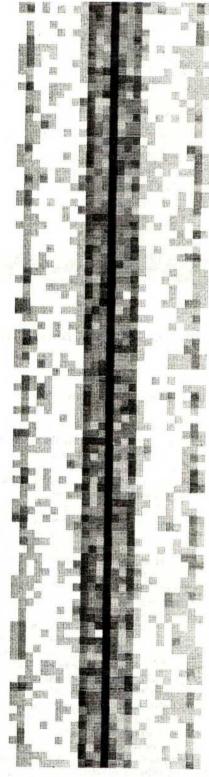

Fig. 2 A plot of the density of the two-dimensional simulation, at Z=0, given the same initial conditions as in the one-dimensional simulation. A small population of particles exists outside the slab, too light to be seen in this rendering.

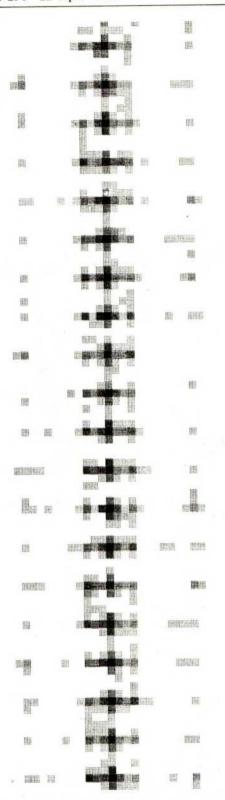

Fig. 3 A plot of the same initial conditions as in Fig. 2, if 1% of the mass is divided between 'protogalaxies' in the caustic surface. The clustering of the test particles is pronounced.

densation is subject to fragmentation by introduction of small 'protogalaxy' mass perturbations in the central plane, and is available for capture by collapsing protogalaxies.

Since many neutrinos would lie beyond the region of galaxy clustering and the Hubble expansion rate may be highly anisotropic, estimates of Ω from observations of the deceleration of galaxies may be incorrect. Therefore the clustering of massive neutrinos to account for the 'hidden mass' on all scales

is not in conflict with simple assumptions, provided that the initial perturbations are sufficiently anisotropic.

I thank D. W. Sciama for support, encouragement and training, S. Weinberg for financial support, and the Department of Physics, University of Texas at Austin for allowing the large amount of computer time needed to conduct this study. A conversation with J. Binney was helpful in planning the study, and N. Sharp assisted in computing.

The Crab pulsar (PSR0531+21) was one of the earliest identified sources of high-energy γ radiation 1-6. As such it was selected as the first object of detailed study by ESA's γ-ray astronomy satellite COS B, launched in August 1975. The experiment and mission have been described elsewhere7. In the first 6 yr of operation COS B has made five observations (each of 30-40 days duration) in which PSR0531+21 was within 15° of the centre of the field of view. The first of these confirmed the result of the SAS 2 experiment that the γ -ray light curve for energies above a few tens of MeV consisted essentially of two equally strong peaks but the later measurements found a decrease in the strength of the second peak relative to the first. No change was observed in the 2-12 keV X-ray light curve simultaneously measured by COS B. The total data from the five observations contain the first evidence of interpulse emission between the two peaks in the energy range 50-3,000 MeV.

The epochs and observing conditions are summarized in Table 1. The accuracy of the on-board clock and the precision of reconstitution of the position of the satellite in its orbit as a function of time permit the measured arrival times of the γ-ray photons to be transformed to the Solar System barycentre (SSB) with an uncertainty of 0.5 ms. In making this transformation the pulsar position measured at radio frequencies8 was used.

The phase ϕ of a γ -ray event with SSB arrival time T is calculated from the frequency f and its derivatives f, f at epoch T_0 according to

$$\phi = \phi_0 + \Delta T f + \frac{1}{2} \Delta T^2 f + \frac{1}{6} \Delta T^3 \tilde{f}$$

where

$$\Delta T = T - T_0$$

The values of these parameters used to analyse the present-observations are given in Table 1. For the first three observations radio parameters were available (ref. 9 and personal communications from V. Boriakoff and D. Ferguson, and J. M. Rankin). For observation 54 use was made of the COS B 'pulsar synchronizer,' a proportional counter sensitive to 2-12 keV X rays¹², the arrival times of which are measured with the same precision as for the γ rays. As there are many more X-ray photons than γ rays, it was possible to determine the pulsar frequency and its first derivative by testing trial light curves for values of these parameters scanned around the extrapolations from earlier epochs. The values adopted are those which gave

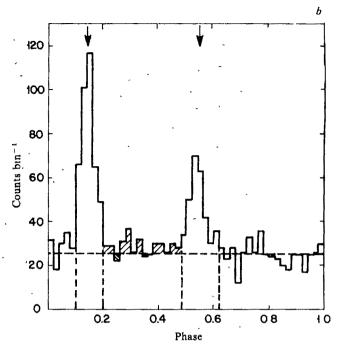

Fig. 1 a, γ -ray light curves of PSR0531+21 at the epochs indicated. Events were selected by energy E and arrival direction θ according to $50 < E < 150 \,\text{MeV}$ and $\theta < 7^\circ$ or $150 < E < 3,000 \,\text{MeV}$ and $\theta < 4^\circ$. The shaded areas indicate the phase intervals of the two pulses and the horizontal broken lines show the level of the background. b, γ -ray light curve obtained by summing the individual curves. The horizontal broken line shows the background level and the shaded area indicates the interpulse emission. The two arrows indicate the phases of the radio peaks.

the X-ray light curve having the highest χ^2 . (For a discussion of the method see ref. 11.) This approach could not be used for observation 44 because the pulsar was outside the field of view of the X-ray detector. Instead the arrival times of the γ rays themselves were used in a parameter scan. The features of the resulting light curve may therefore be over-emphasized but this observation is trivial in the final conclusions.

High-quality y-ray events were selected from the data by applying established and calibrated criteria to the sparkchamber pictures and counter pulse-height measurements. The energy spectra of the pulsar γ rays¹² and of the background radiation are such that the best signal-to-noise ratio is obtained within the energy range 50-3,000 MeV. To take account of the variation with energy of the instrument response (effective sensitive area and angular resolution) the data were analysed in two separate energy ranges, 50-150 MeV and 150-3,000 MeV. Within each range the signal-to-noise ratio could be further optimized by selecting events for which the measured arrival direction fell within a limiting cone centred on the direction of the pulsar. The half angle of the optimum cone was found to be 7° in the lower energy range and 4° in the upper. Figure 1a shows the y-ray light curve for each observation obtained by summing the respective curves for the two ranges. These curves show the actual numbers of photons recorded in each phase bin. Absolute fluxes are not presented. because their accurate determination depends on the analysis of the temporal development of the instrument's sensitivity over the five years and this analysis is still in progress.

Figure 1a shows clearly that for the later observations the second pulse in the light curve is weaker relative to the first than it is in the first observation. For a more quantitative study phase boundaries were assigned to the two peaks, namely 0.10-0.20 and 0.48-0.62 respectively. A background level, above which 'pulsed counts' were measured, was derived as the mean level in the phase interval 0.62-0.10. This background includes not only the instrumental background, the general

galactic emission and any isotropic radiation but also any continuous (unpulsed) emission from the pulsar itself or the Crab nebula. The two peaks and the background levels are indicated in Fig. 1a.

Added together, the light curves of Fig. 1a yield Fig. 1b which represents the best available database on the high-energy y-ray emission from the Crab pulsar and contains the first positive evidence in the energy range 50-3,000 MeV for highenergy y-ray emission in the 'interpulse region' between the two peaks of the PSR0531+21 light curve. Averaged over all the observations this amounts to $(15\pm4)\%$ of the total pulsed emission (that is the phase interval 0.10-0.62) in the energy range 50-3,000 MeV. This is not inconsistent with the upper limit of 15% derived earlier from the first observation alone¹³ and is about half of the corresponding contribution in the case of PSR0833-45 (ref. 14). Within the wide limits of error, there is no evidence for any variation with time in the relative flux in the interpulse region. An evaluation of the phase difference between the two peaks in Fig. 1b gives 13.0 ± 0.5 ms, in agreement with corresponding measurements at radio, optical and X-ray wavelengths^{15,16}. It is also possible to measure the peak widths which are found to be 1.6 ± 0.4 ms (FWHM) and $2.0\pm$ 0.5 ms (FWHM) respectively.

The light curves shown in Fig. 1 represent only a fraction of the photons from the pulsar, that is those with measured arrival directions, θ , (relative to the pulsar direction) within the selection cones. To obtain the best estimate of the total numbers of photons the distributions of their arrival directions were fitted with the point-spread function describing the instrument's angular resolution appropriate to the energy range and to the aspect angle, α , of the observation. This point-spread function is approximated by the expression¹⁷

$$h(\theta) = 2\pi\theta \exp(-(\theta/\theta_0)^{2c})$$

where c=0.8 for 50 < E < 150 MeV and 0.5 for 150 < E < 3,000 MeV. The value of θ_0 decreases with aspect angle in the lower energy range, from 4.8° at $\alpha=0^\circ$ to 4.3° at $\alpha=15^\circ$ and increases in the higher range, from 1.2° at $\alpha=0^\circ$ to 1.75° at $\alpha=15^\circ$.

Separate fits were made for each observation in each energy range and for the photons having phases within each of the two peaks. By integrating the fitted curves the total numbers of events contributing to each peak, P_1 and P_2 respectively, were determined. The ratio of the strengths of the two peaks was calculated and the results are presented in Table 1. These show that during the first observation the second peak was significantly stronger (relative to the first peak) than at later times. The effect is present in both energy ranges but is more pronounced below 150 MeV. Using a χ^2 analysis it has been found that the chance probability of the total effect is $\sim 5\%$.

The results presented here show no evidence for any change in the γ -ray light curve between 1976 and 1980. The departure from the mean lies in the earlier (1975) measurement. That result is consistent with the light curve measured by SAS 2 at energies above 35 MeV in 1972 and 1973¹⁸. It is estimated that, taking phase intervals as close as possible to those used in analysing the COS B data, the ratio of the second pulse to the first was 1.33 ± 0.39 at the time of the SAS 2 observation. This ratio is plotted together with those from COS B in Fig. 2. The probability that all these results represent chance fluctuations about a common mean is <1% combining a run test with the χ^2 analysis.

In a preliminary presentation of these results¹⁹ the γ -ray light curves for the Vela pulsar PSR0833-45 were also given for a similar time interval. No variation in the shape of the light curves was observed for that pulsar.

The measured variation in the Crab pulsar light curve cannot be ascribed to a change in the sensitivity of the instrument unless that change was energy dependent and the two pulses have markedly different energy spectra. Bennett et al.¹³ found no evidence for spectral differences sufficient to account for the effect seen here. Furthermore, a possible sensitivity change is not sufficiently energy dependent to influence the measured light curve of PSR0833-45 ¹⁹, for which the second pulse is known to have a harder spectrum than the first¹⁴.

The pulsar synchronizer on board COSB has allowed the long-term behaviour of the 2-12 keV X-ray light curve of the pulsar to be studied. Figure 3 shows the results for the three observations when the pulsar was within the field of view of the proportional counter. The shapes of these light curves exhibit excellent reproducibility. The same situation applies at

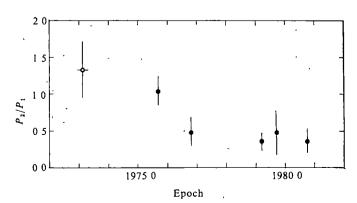

Fig. 2 Variation with time of the fraction of pulsed counts in the second pulse: ○, >35 MeV from SAS 2 data¹⁸; ●, 50-3,000 MeV from COS B data (present work).

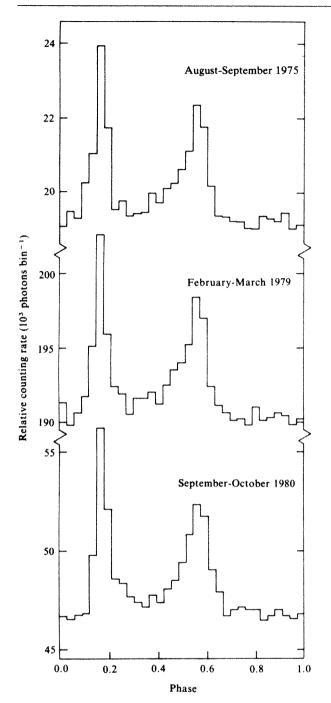

Fig. 3 X-ray (2-12 keV) light curves measured during observations 1, 39 and 54.

optical wavelengths where very small limits have been placed on the variation of the light curve²⁰. Above ~20 keV a decrease in the relative strength of the second X-ray peak between observations in 1969-70 ²¹⁻²³ and in 1974 ²⁴ has been claimed²⁵. However, the effect is probably due to differences in the definitions of the phase intervals of the two peaks by the original investigators. In low energy (1-20 MeV) γ rays light curves of the same shape were measured in October 1977 and May 1979 26 but over this limited time span there is no evidence in the COSB result for any variation. In the ultra-high energy range (>100 GeV) a variation in the strengths of different components of the light curve between 1971 and 1973 has been reported27

The observed variation in the high-energy light curve could be due to a change in the emission modes in one of the polar regions of the magnetosphere of the neutron star, but also to a change in the geometry, such as a decrease in the angle

between the magnetic and rotational axes. Whatever the explanation, the absence of the effect in the X-ray light curve points to different emission regions and/or production processes in the two energy ranges. The properties of the different components of the radio light curve support the presence of two beaming mechanisms ^{28,29}. Different emission regions or beaming geometries have also been proposed to account for differences between the radio, optical and y-ray light curves of PSR0833-45 (refs 28-30).

We thank Drs J. M. Rankin, V. Baroakoff and D. Ferguson for communicating radio data and Dr I. I. Shapiro for making available the MIT barycentric ephemeris.

Was the 1970 geomagnetic jerk of internal or external origin?

S. R. C. Malin & B. M. Hodder

Institute of Geological Sciences, West Mains Road, Edinburgh EH9 3LA, UK

Annual mean data from worldwide magnetic observatories show that there was a jerk (step-change in the second time derivative) in the geomagnetic field, which took place over an interval of <2 yr around 1970. If such a short-lived phenomenon originated in the Earth's core, and were still detectable after passing through the mantle to the surface, this would imply a much lower conductivity for the lower mantle than had been believed previously. Here we show by an objective test that most of the jerk has an internal origin.

The geomagnetic field has a rich spectrum of temporal changes from audio frequencies to thousands of years. In general, the short-term variations (with time scales of a year or less) are of external origin relative to the Earth's surface, though they have a smaller internal component due to electromagnetic induction in the conducting layers of the Earth. The long-term variations, with time scales of several decades, are of internal origin. At intermediate time scales the picture is less clear; there are certainly external variations with a period of ~11 yr, associated with the sunspot cycle, and there are variations that occur over a few years which seem to be of internal origin. These short-term variations are of particular interest because, it they are real and originate from the Earth's core, they place constraints on the conductivity of the mantle through which they have to pass before being detected at the surface2

In 1967, using accepted values for the mantle conductivity, Currie³ deduced that no core signal with a period of ≤4 yr could penetrate the mantle and that all observed variations on a shorter time scale must be of external origin. Later, Alldredge4 raised this limit to 15 yr and suggested a correspondingly higher value of mantle conductivity. Other authors prefer lower conductivities and time scales.

The most convincing evidence for the lower values comes from the change in geomagnetic secular acceleration that occurred over an interval of 1 or 2 yr around 1970. This event was first reported by Courtillot et al.8 (although Mizuno had submitted an article nearly a year earlier describing similar effects for 1965 and 1974 restricted to the region of Japan) and has since been widely studied⁷⁻¹⁵. Although the effect is worldwide 14,15, it is most clearly seen in declination data from European observatories. See, for example, Fig. 1a, which shows plot of 3 yr running means of declination observed at Eskdalemuir, Scotland, and Fig. 1b, the first derivative of these data (secular variation) obtained by differencing successive means. The secular acceleration is the slope of curve b. It is reasonably constant before 1970 but changes suddenly at about that date to a new value, at which it remains for the rest of the interval shown.

The reality of this phenomenon, its worldwide distribution and the short interval over which it occurs are firmly established. However, although most authors 11,15 believe the effect to be of internal origin, their reasons for this are based on morphological arguments rather than objective measurement, and there are others 16,17 who believe that all such short-period variations are of external origin. We present here an objective separation into parts of internal and external origin and compare their sizes.

Gauss¹⁸ originally developed the method of spherical harmonic analysis to determine whether the main geomagnetic field was of internal or external origin, and the method may equally well be applied to time derivatives of the geomagnetic field. Here, we apply it to the change of secular acceleration that occurred around 1970. The data are annual mean values of the geomagnetic north, east and vertical components from the 83 observatories that operated throughout the interval 1961.0-1978.0 (ref. 19). For each observatory and element, means were formed for the centre of each even year by forming $(x_{n-1}+2x_n+x_{n+1})/4$, where x_n denotes the annual mean value for year n, giving eight bi-annual means, denoted (1)-(8). The pre-1970 secular acceleration was defined as [(1)-(2)-(3)+ (4)]/2 and the post-1970 secular acceleration as [(5)-(6)-

All coefficients that exceed their standard deviation are included, up to maximum degree and order 4.

(7)+(8)]/2. The jerk¹ is simply the difference between these quantities.

In the analysis, it is assumed that the jerk may be adequately represented by the spherical harmonic expansion of a potential field up to maximum degree and order 4 for both internal and external terms. The spherical harmonic coefficients are obtained by the method of least squares, solving for internal and external coefficients simultaneously, and evaluating their standard deviations in the usual way from the sum of squares of residuals, number of degrees of freedom and the leading diagonal of the inverse matrix. After some experiment with different sets of coefficients, the solution including all those that exceed their standard deviations and omitting all those that do not was found to be that given in Table 1. Following recommended geomagnetic practice²⁰, the coefficients are in the Schmidt quasinormalized form.

It is immediately obvious that most of the jerk is of internal origin: the mean square value21 of the internal part exceeds that of the external part by a factor of 3.4 ± 0.8 . Of the 10 largest coefficients, only 2 are for the external part. The larger of these, g_1^{0e} (using the notation of Chapman and Bartels² represents the field due to a ring of current above the Equator, which is precisely what would be expected for the external contribution. The only other external coefficient to exceed 1 nT yr^{-2} is $h_2^{2\epsilon}$; there is no obvious external source which would produce this term. The three coefficients that exceed 2 nT yr⁻² $(g_1^{0i}, h_2^{1i}, h_3^{1i})$ are all of internal origin. Part of the g_1^{0i} term could be due to induction by the current represented by g_1^{0e} , but, even if the whole Earth were a perfect conductor, this could not account for more than 0.74 nT of g_1^{0i} (ref. 23). We would not expect, and we do not find, any obvious pattern to the internal part, except the tendency15 for the coefficients to decrease in amplitude with increasing n. This tendency, which is more obvious when the coefficients are fully normalized, suggests that the jerk originates deep within the Earth rather than near the surface.

We conclude that internal sources can give rise to changes in secular variation on time scales as short as 1 or 2 yr and that these were indeed the major factor in the geomagnetic jerk that occurred around 1970.

Intensity of the geomagnetic field near Loyang, China between 500 BC and AD 1900

Q. Y. Wei, D. J. Li, G. Y. Cao, W. S. Zhang & S. P. Wang

Institute of Geophysics, Academia Sinica, Peking, China

There are remarkably few data on the intensity of the geomagnetic field in early China. New results reported here indicate that the total intensity of the magnetic field of the Earth in the region near Loyang (lat. 34°42' N, long. 112°40' E) has changed considerably during the past 2,400 yr (500 BC-AD 1900). The maximum value reached about 1,700 yr ago is as much as 54% higher than the present one.

Loyang is the ancient capital of nine dynasties, so samples collected from the city and nearby regions are suitable for archaeomagnetic research. The samples used in the present work are mainly of three types: (1) baked earth from ancient pottery or brick kilns and ovens in residential structures; (2) grave bricks-some of them are engraved with accurate dates and place of their baking; (3) bricks from ancient structures such as buildings and city wall.

Table 1 gives the relevant data on samples collected from Loyang and Zhengzhou. The stability of the primary remanent magnetization was tested in all the samples and proved satisfactory1. The magnetization of the specimens was measured with an astatic magnetometer. The total intensity of the geomagnetic field was inferred from stepwise thermal demagnetization^{2,3} with temperature steps of 40-60 °C from 100 to ~600 °C. The slope of the natural remanent magnetization-partial thermal remanent magentization (NRM-PTRM) straight line was calculated using the method of least squares. The points in the

NRM-PTRM diagram which deviated systematically at low and high temperatures from a straight line were discarded.

The averaged data for each dynasty were obtained by using the method we have described earlier4, and are given in Table 1. Figure 1 shows variation of the total intensity of the geomagnetic field during the past 2,400 yr. The horizontal error bars represent the archaeological estimate of the duration for each epoch (or dynasty); the vertical error bars represent the standard deviation.

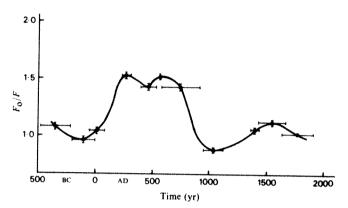

Fig. 1 The change in the ratio of the ancient intensity of the geomagnetic field, F_0 , to the present-day value F_0 in Loyang region.

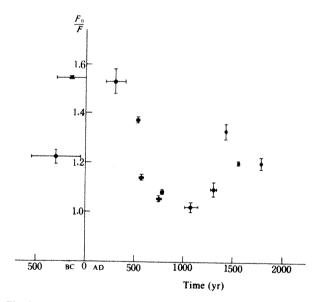

Fig. 2 Ratio of intensity of the ancient geomagnetic field (F_0) to that at present (F) in Japan³.

	Table 1 Data of samples from Zhengzhou and Loyang								
Sampling site	Lat. N	Long. E	Dynasty	Age	Sample type	N	F_0/F	F ₀ (Oe)	δF
Zhengzhou	34°54'	113°39′	Zhanguo	475-221 BC	Grave brick	2	• • • • • • • • • • • • • • • • • • • •		
Loyang	34°42′	112°40′	Western Han	206 BC-AD 8	Baked earth		1.09	0.60	0.01
Loyang	34°42'	112°40'	Han (Wang Mon)			4	0.96	0.53	0.01
Loyang	34°42′	112°40′	Wei-Jin	AD 9-23	Grave brick	. 5	1.05	0.58	0.01
Loyang	34°42′			AD 220-300	Brick, baked earth	2	1.54	0.85	0.01
		112°40′	Northern Wei	AD 386-534	Baked earth	3	1.43	0.79	0.02
Loyang	34°42′	112°40′	Northern Qi	AD 562-565	Grave brick	11	1.53	0.84	0.01
Loyang	34°42′	112°40′	Sui-Tang	AD 581-907	Brick, baked earth	10	1.43		
Loyang	34°42′	112°40′	Northern Song	AD 960-1127				0.79	0.02
Loyang	34°42′	112°40′	Early Ming		Brick, baked earth	8	0.88	0.48	0.01
Loyang	34°42′			AD 1368-1435	Brick	2	1.06	0.58	0.01
. , .		112°40′	Ming	AD 1436-1661	Brick	2	1.13	0.62	0.01
Loyang	34°42′	112°40′	Qing	AD 1631-1911	Brick	4	1.03	0.57	0.01

 F_0 , ancient intensity of the geomagnetic field; F, present-day intensity. N, number of samples.

3

It is clear from Fig. 1 that the total intensity of the geomagnetic field in the region near Loyang has changed. Between 400 BC and AD 1900 there are two minima, at about 100 BC and AD 1100, one (main) bimodal maximum between AD 250 and 600, and a smaller maximum at about AD 1550. The difference between the maximum (~85 µT) and both minimum values (~53 μT and ~48 μT respectively) amounts to about 37 µT. The length of time between the two minima is about 1,200 yr.

It is interesting to compare these data with those obtained from other locations in the world. For example, comparison of the results from Loyang with those given in ref. 5 indicates that they are broadly similar although the details vary. Moreover the variation of the ratio of the total intensity in early Japan to that in present-day Japan³ is in a good agreement with that for Loyang both in tendency and magnitude of changes during the past 2,400 yr, although there is a time delay over the whole interval (see Fig. 2). This is also the case in comparisons with data from Athens⁶, Czechoslovakia and central America⁷. It may be related to the westward drift of the non-dipole field.

We thank Drs Xu Jing-yuan and Huang Ming-lang for supplying samples used in work on the secular variation of the total intensity as well as on the direction of the ancient geomagnetic field, and Professor J. A. Jacobs for reading the manuscript and for valuable comments.

A spinel to β -phase transformation mechanism in (Mg,Fe)₂SiO₄

G. D. Price & A. Putnis

Department of Geology, University of Alberta, Edmonton, Alberta, Canada T6G 2E3

Olivine of approximate composition Mg1.8Fe0.2SiO4 is a major constituent of the Earth's upper mantle. Structural changes, which occur in olivine as a function of increasing pressure and which involve the formation of the β -phase and spinel structure, γ -phase polymorphs, have therefore aroused considerable interest¹⁻⁴. The mechanisms of these transformations are of particular importance because of their effect on the properties of the mantle in the zone in which they occur. Several mechanisms have been proposed4-7, but remain controversial in the absence of sufficient observational data on intergrowths of reactant and product phases. Although these phases have been produced experimentally2, direct observations of such intergrowths have generally been made only on natural material from shock-produced veins in chondritic meteorites^{5,6,8}. Here we report observations made on the natural, high-density polymorphs of (Mg,Fe)₂SiO₄ found in the Peace River meteorite, which reveal that the mechanism for the spinel to β -phase transformation involves the topotactic replacement of the spinel polymorph by single, β -phase grains.

We have previously described^{5,6} the microstructures in the spinel polymorph of (Mg,Fe)₂SiO₄ (ringwoodite) from the Tenham chondritic meteorite, and suggested that the defects (Fig. 1 in ref. 5) found in the spinel were due to the partial inversion of ringwoodite to the β -phase. The defects found in the spinel lie on $\{110\}$ planes, and contrast analysis indicates^{6,8} that for a (110) defect, the displacement vector is of the type a/4[110], or equivalently $a/4[1\overline{1}2]$ (refs 8.9). The defects are therefore stacking faults, which may be viewed either as Frank-type faults corresponding to the removal of a stoichiometric (Mg,Fe)2SiO4 layer accompanied by an a/4[110] displacement, or as Shockley-type faults corresponding to an $a/4[1\overline{1}2]$ shear. Stacking faults of this type leave the oxygen sub-lattice unaffected, but change the cation distribution so that in the fault plane the structure is that of the β -phase. The spinel and β -phase structures are closely related 10,11, and indeed the spinel structure can be completely transformed into that of the β phase by the introduction of two a/4[110] (110) stacking faults per unit cell. The transformation of spinel to β -phase may, therefore, be considered relatively simple, and one which would, in suitable conditions, be favoured kinetically over the reconstructive inversion to olivine. In this respect, our conclusions differ from those of Madon and Poirier⁸ who assume that the faults in ringwoodite result from the impingement of spinel domains nucleated at various places within the olivine crystal during the prograde transformation, rather than being associated with a post-shock, retrograde process. Here, we present further evidence to support our suggestion that the development of stacking faults in the spinel phase is indeed related to the mechanism of the spinel to β -phase transformation.

The Peace River meteorite¹² (classified as an L6 olivinehypersthene chondrite) contains shock-produced veins, which pervade the body of the meteorite in much the same way as the veins found in other shocked chondrites (for example, Tenham, Coorara, Catherwood and Coolamon)¹³⁻¹⁶. In fragments found within these veins, the constituent olivines and hypersthenes have been transformed to their high-density polymorphs, ringwoodite and the garnet-structure majorite respectively. In general, these 'high-pressure phases' have remained, quenched-in after an extraterrestrially produced shock event. The vein studied in the Peace River meteorite differs significantly, however, from those described in other meteorites, in that it contains significant quantities of the β -phase polymorph of $(Mg, Fe)_2SiO_4$. The β -phase occurs as microcrystalline aggregates which pseudomorph previously existing olivine fragments within the vein. The fragments rarely exceed 0.5 mm in diameter. Electron microprobe analyses of β -phase aggregates yield an average, ideal formula for the observed β -phase of (Mg_{1.4}Fe_{0.5}Mn_{0.1})SiO₄. Representative analyses of a β-phase aggregate and an untransformed olivine are given in Table 1; within experimental limits, no compositional differences between the (Mg,Fe)₂SiO₄ polymorphs could be detected. Least-squares refinement of X-ray powder data obtained from separated β -phase fragments yielded orthorhombic cell parameters of a = 5.70(2), b = 11.51(7) and c = 8.24(4). The calculated cell volume for the observed β -phase is 541(3)Å, and with z = 8, the calculated density on the basis of the idealized formula is 3.84 g cm⁻³.

Transmission electron microscopy (TEM) shows that relatively large fragments within the shock-vein are composed of granular aggregates of well formed, micrometre-size β -phase grains, with intergranular boundaries usually meeting at triple points (often with interfacial angles close to 120°). Grains of β -phase are also found replacing grains of ringwoodite (Fig. 1). The spinel grains invariably carry a high density of a/4110 stacking faults (identical to those found in the Tenham meteorite^{5,6}). There is an occasional slight (±2°) misalignment of the β -phase lattice relative to the spinel lattice, but electron diffraction confirms that the phases are essentially orientated such that $[010]_{\theta} | [110]_{\gamma}$ and $[001]_{\theta} | [001]_{\gamma}$. The phases share, therefore a continuous, near cubic-close-packed oxygen sublattice.

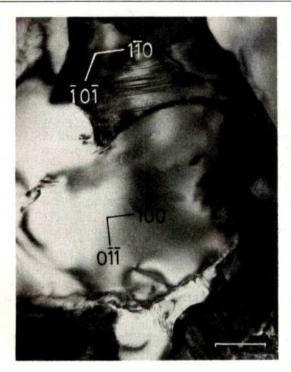

Fig. 1 Electron micrograph of a fault-free β -phase grain, topotactically replacing faulted ringwoodite. The two phases are related such that $[010]_{\beta} ||[110]_{\gamma}$ and $[001]_{\beta} ||[001]_{\gamma}$. A subgrain boundary separates the two phases, but other examples were found which had coherent interfaces. Scale bar, 0.2 µm.

The textures observed are interpreted as resulting from postshock inversion of the spinel polymorph to a lower density phase, in response to a reduction in pressure. The proposed mechanism for the observed transformation of spinel to the β-phase involves two stages. The process initially is a cooperative or martensitic one, and probably proceeds by the propagation of low-energy¹⁷, Shockley partial dislocations of the type 1/4[112] (110) through the spinel, to produce the observed stacking faults on {110} planes. These faults form on all {110} sets of planes in the spinel, however, and prevent the simple cooperative formation of a single, β -phase grain from the host spinel (a process which would require faults on only one set of (110) planes). As the density of faults increases, a critical volume of β -phase is produced locally, which then grows and topotactically replaces the host. As the β -phase region grows, the faults in the spinel are swept before the advancing interface (Fig. 1) to produce a relatively fault-free grain of β -phase. Occasionally, relict faults are found in the β -phase grains (Fig. 2), which high resolution electron microscopy has shown to be of the type 1/4[010] (010) (expressed in terms of the β -phase lattice), and which are therefore complementary to those found in

Table 1 Electron microprobe analyses of β -phase aggregates and shocked olivine crystals form the Peace River meteorite

	β-phase (wt%)	Olivine (wt%)
SiO ₂	38.37	38.16
Al ₂ O ₃	0.00	0.00
Cr ₂ O ₃	0.00	0.00

CaO	0.05	0.00
MnO	0.31	0.40
FeO	23.10	23.57
CoO	0.20	0.00
NiO	0.11	0.05
Total	100.45	100.56

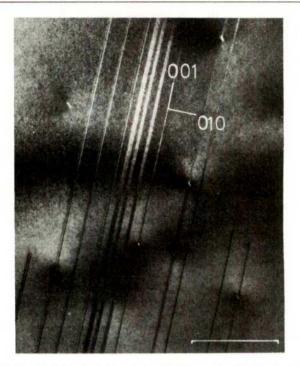

Fig. 2 Residual faults found in a β -phase grain. The faults are of the type 1/4[010] (010), and gives rise to the spinel cation distribution within the fault plane. Faults are terminated or displaced at dislocations. Scale bar, 0.1 µm.

spinel, that is locally retaining the spinel cation distribution within the β -phase matrix. The faults are often complex in detail and are frequently terminated at dislocations within the grains. They are interpreted as being residual features preserved as a result of the relatively rapid, post-shock growth process, and are the subject of continuing research.

The spinel to β -phase inversion is expected to occur^{7,18} within the mantle, at a depth close to 400 km, as a result of the peritectoidal relationship between the olivine, spinel and β phase polymorphs of magnesium-rich members of the (Mg,Fe)2SiO4 system. However, considering the different thermal regimes involved, it is difficult to assess whether the transformation of spinel to β -phase occurs in the mantle by the same mechanism as the one which has been inferred from the textures in the Peace River meteorite. A mechanism of this type occurring in the mantle would have as the rate-controlling step the diffusion of atoms across the β -phase/spinel interface. The initial cooperative or martensitic stage of the mechanism would, however, particularly weaken the spinel with respect to shearing stresses on {110}. Suitable shears may allow the transformation to proceed to completion by a single, military process, and in this case, the rate-controlling step would be the formation and glide of partial dislocations through the spinel lattice. On the basis of these suggested mechanisms, it may be inferred, therefore, that the overall kinetics of the spinel to β -phase phase transformation will be particularly sensitive to shear. In addition, the resistance of spinel bearing mantle to shear stresses would be significantly reduced during the transformation to the β-phase, and would affect mantle rheology.

We acknowledge the help and advice of Dr S. O. Agrell, and the NERC for electron microscope facilities. G.P.D. also acknowledges the receipt of Research Fellowships from the NERC and from Clare College, Cambridge.

Winchite and the actinolite-glaucophane miscibility gap

W. V. Maresch, O. Medenbach & A. Rudolph*

Institut für Mineralogie, Ruhr-Universität Bochum, D-4360 Bochum, FRG

Leake et al.1 have recently emphasized the apparent scarcity of winchite s.l., NaCa(Mg, Fe²⁺)₄(Al, Fe³⁺) [Si₈O₂₂/(OH)₂] (ref. 2), an amphibole intermediate in composition between the glaucophane-riebeckite series of high-pressure blueschists and the tremolite-actinolite series of lower-pressure greenschists. The rarity of winchite is considered consistent with the existence of a miscibility gap^{3,4} between these two amphibole series at the metamorphic P-T conditions normally attained in nature. Here we present optical and X-ray properties of Mg- and Al-rich winchite from Venezuela and draw attention to several other recent winchite analyses. In fact, as Schliestedt's new data on co-existing sodic and calcic amphiboles in blueschists show, only the present Mg-Al-rich winchite definitely lies within the above miscibility gap.

Winchite was identified in an amphibole-eclogite found in talus near El Valle del Espiritu Santo, Margarita Island, Venezuela (63°53'10" W, 10°58'55" N; Venezuela grid ref. no. 40322142). Field relationships of similar occurrences on Margarita indicate that the eclogite is a metabasalt pod in quartzmica schist of epidote-amphibolite facies grade. The bulk-rock chemistry of the eclogite indicates a tholeiite of MORB affinity6. Winchite is found with omphacite, garnet, rutile and quartz, as well as with minor epidote, albite, opaque oxide, sphene and apatite. Thin actinolitic rims overgrow some of the winchite grains.

Electron microprobe analyses (Table 1) indicate that the amphiboles are winchites grading to alumino-winchites (Al> 1.0)2. Figure 1 shows that the departure from ideal end-member winchite composition is due mainly to a minor amount of edenite substitution, (Na, K) + Al - Si, giving A-site occupancy totals of 0.02-0.18 atoms per half-unit-cell formula, and more $(Al, Fe^{3+}) + Al \rightarrow$ substitution, Tschermak's extensive (Mg, Fe²⁺)+Si, leading to Si totals of 7.56-7.78. Figure 1 also gives published data of samples that classify as winchite, although the samples are markedly more iron-rich and would be classified as ferro- or ferri-winchite2. All analyses are from blueschist terranes. Clearly, winchites approaching the ideal end-member are not uncommon in nature.

We have determined the optical and X-ray properties of the Venezuelan winchite (Table 2) on a single cleavage fragment $\sim 50 \times 50 \times 200$ µm in size. The optical properties were corroborated on several other fragments and are considered to be representative. Indices of refraction and 2V were measured using the microrefractometer spindle stage of Medenbach⁷, while X-ray data were collected on a four-circle automatic diffractometer. A scan of 278 reflections between 0 and 35° MoK_{α} revealed no reflections violating monoclinic C symmetry.

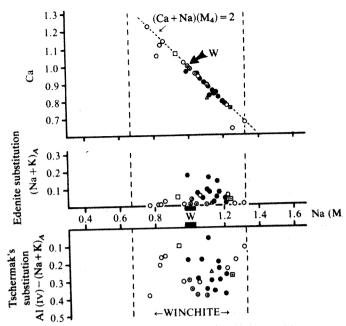

Fig. 1 Plot of $Na(M_4)$ against edenite substitution, $(Na+K)_A$, Tschermak's substitution, Al (IV)-(Na+K)A, and Ca all referred to half-unit-cell formula. Data sources: •, present study; O, ref. 5; □, ref. 14; △, ref. 8; ○, ref. 15; □, ref. 9. Fe³⁺/Fe² for all analyses are calculated as for Table 1. W, ideal end-member winchite.

Table 1 Representative microprobe analyses of Venezuelan winchite

Ana	lysis 1.1 (alumino-	winchite)	Ar	ialysis 8.2	(winchite	e)
Ana SiO ₂ TiO ₂ Al ₂ O ₃ Fe ₂ O ₃ FeO MnO MgO CaO Na ₂ O K ₂ O Total	55.00 	Si Al Total Al Ti Fe ³⁺ Fe ²⁺ Mn Mg Total Ca Na K	7.70 0.30 8.00 1.04 - 0.37 0.83 0.01 2.75 5.00 0.83 1.21 0.02 2.06	SiO ₂ TiO ₂ Al ₂ O ₃ Fe ₂ O ₃ FeO MnO MgO CaO Na ₂ O K ₂ O Total	54.41 0.20 7.00 4.72 6.09 0.04 14.25 6.32 4.01 0.16 97.20	Si Al Total Al Ti Fe ³⁺ Fe ²⁺ Mn Mg Total Ca Na K	7.63 0.37 8.00 0.79 0.02 0.50 0.71 0.01 2.97 5.00 0.95 1.09 0.03 2.07

The Fe3+/Fe2+ ratio was calculated by normalizing tetrahedral and octahedral occupants to 13 at constant 23 oxygens. This procedure is acceptable for sodic-calcic amphiboles

There is no evidence of exsolution. Table 2 shows that the optical and unit cell properties of Venezuelan winchite lie between those of tremolite and glaucophane, as expected.

The occurrence of winchite amphibole has been interpreted by Brown⁸ and Green and Spiller⁹ to indicate closure of the tremolite/actinolite-glaucophane/riebeckite miscibility gap. Recent data from Schliestedt⁵ on coexisting amphibole pairs from Sifnos, Greece, indicate, however, that the multidimensional nature of the miscibility gap must be considered. Two projections of the latter, based on Schliestedt's data, are given in Fig. 2. Although the exact shape of the miscibility gap in $Na/Na + Ca - Fe^{2+}/Fe^{2+} + Mg - Fe^{3+}/Fe^{3+} + Al$ space is unknown, simple geometrical reasoning suggests that only the Venezuelan winchite appears to lie in the gap with any certainty. Thus only magnesian, alumino-winchites indicate P-T conditions exceeding the critical temperature of the gap. Iron-rich

winchite can be stable in normal blueschist-facies conditions where magnesian, alumino-winchite is not. Thus the latter should not be found in typical blueschists.

The upper temperature stability limit for winchite is unknown. For most common metabasaltic compositions metamorphosed in intermediate- to high-pressure conditions, however, increasing Tschermak's substitution with increasing temperature in the amphibole of the basic assemblage will lead to more Si-deficient amphibole compositions such as barroisite or hornblende. Thus the common range of P-T stability of magnesian, alumino-winchite must be severely restricted. For Venezuelan, winchite-bearing amphibole Rudolph⁶ has estimated equilibration conditions of at least 10 kbar and 600 ± 30 °C for the pyroxene-garnet pair, but it is not clear whether winchite growth was approximately coeval or occurred significantly later in the metamorphic cycle.

We thank W. Gebert for supplying the X-ray data, and W. Schrever and R. Grapes for helpful discussions. The research was partly supported by grant Ma 689/1 of the Deutsche Forschungsgemeinschaft, Bonn, to W.V.M.

History of the continental lithosphere recorded by ultramafic xenoliths

Claude J. Allègre, Nobu Shimizu* & Dominique Rousseau

Laboratoire de Geochimie et Cosmochimie, Institut de Physique du Globe de Paris, Université de Paris 6, 75230 Paris Cedex 05, France

Since the development of the plate tectonic theory, the formation, structure and properties of the continental lithosphere have been widely debated1-3. By analogy with petrological models for the oceanic lithosphere generated at ridges4-6, the continental lithosphere has been interpreted in terms of a comprehensive mechanical and petrogenetic unit by considering, for example, that the continental crust was differentiated through a process such as zone melting, the lithospheric mantle being the residue of this extraction process^{7,8}. However, geological observations show that formation of the continental crust was quite complex, including sedimentation, metamorphism and orogenesis, and not simply direct magmatic segregation. Underneath its crust, the continental lithosphere, mainly comprises peridotites and in this respect, it resembles the oceanic lithosphere. This similarity, which is corroborated by seismic data, does not, however, mean that a chemical coupling exists between the subcontinental lithospheric mantle and continental crust in a similar way as for the oceanic lithosphere. Although magma generation and eruption through the continental lithosphere contribute to the growth of the continental crust and to the depletion of the subcontinental lithospheric mantle in incompatible elements, no simple chemical coupling should exist if the continental lithosphere were created by thermal accretion. The petrology and geochemistry of the continental lithosphere can also be studied using xenoliths brought up to the surface by kimberlitic or alkalic volcanics. This technique attracted much attention because of the determination of pyroxene geotherms9 and the claim that it permits the description of the palaeogeothermal structure of continents and oceans 10,11. Although some of the original conclusions seem premature12 the basic idea is sound. We have now used radiogenic tracers, the ⁸⁷Rb-⁸⁷Sr system, to study the creation of the continental lithosphere. We present here results on garnet lherzolite xenoliths from southern African kimberlites and discuss their geochemical and geodynamical implications.

The major and trace element chemistry of the constituent minerals of most of the samples studied here (see Table 1) has been described elsewhere¹³. The olivine-bearing xenoliths in kimberlites can be ascribed to two textural groups: granular peridotites and sheared lherzolites. Whereas the sheared samples have a 'pristine-mantle-type' chemical composition, the granular ones show a very complex chemistry, depleted in the basaltic components while enriched in some trace elements. Clear evidence for mantle metasomatism has also been reported¹³ for some granular samples.

To study the isotopic characteristics of xenoliths, the minerals enriched in the elements of interest and which are insensitive to secondary reaction processes must be separated. Thus, we separated diopside and garnet as they are the main carriers of

Sr and Rb in these rocks. Separation was done by hand-picking, the purity was checked under a microscope and the separates were washed in high-purity acetone and water to eliminate any surface contamination. The Sr isotopes were analysed using the technique described in ref. 14; the blanks and the results on the standards are given in Table 2. Rb and Sr concentrations were obtained by an isotope dilution technique.

The analytical results summarized in Table 3 show that diopsides have very low Rb/Sr ratios and thus tend to fossilize the ⁸⁷Sr/⁸⁶Sr initial ratio of a mineral assemblage. The observed variation in strontium isotopic composition among diopsides (0.70245–0.70512) clearly demonstrates the heterogeneity of the initial ratio for the continental lithospheric mantle at the time of the kimberlite eruptions.

Such an heterogeneity may reflect either an intrinsic isotopic heterogeneity of the mantle rocks if the assemblages are in internal equilibrium, or different episodes of formation of the continental lithosphere corresponding to the different initial ratios. In an attempt to answer this question we also analysed the garnets, which are the second largest reservoir of Sr after diopside.

The most remarkable result is that diopside and garnet in a given granular sample have very similar ⁸⁷Sr/⁸⁶Sr ratios, whereas the sheared lherzolites yield very different Sr isotope

ratios for these minerals. In other words, considering the ⁸⁷Sr growth since the time of kimberlite eruption, diopside and garnet are close to internal isotopic equilibrium for the granular xenoliths while they are in isotopic disequilibrium for the sheared samples. This behaviour is most surprising in the light of the geothermometry data, as the granular xenoliths typically yield a temperature around 1,000 °C compared with 1,300 °C for the sheared samples. How can rocks with large crystals such as the granular samples be isotopically homogenized at 1,000 °C whereas higher temperature facies with a finer grain-size are in isotopic disequilibrium?

If the rate of re-equilibrium (presumably controlled by the diffusion rate of elements in minerals) were much greater for the major elements than for Rb and Sr, the Sr isotopic disequilibrium could be preserved while the major elements would be completely re-equilibrated. Diffusion of major and trace elements in silicate minerals is still poorly understood. Recent

work¹⁵ on Ca self-diffusion suggests a diffusion coefficient varying from $7.0\times10^{-12}\,\mathrm{cm^2\,s^{-1}}$ to $2.2\times10^{-11}\,\mathrm{cm^2\,s^{-1}}$ between 1,300 and 1,200 °C, respectively, with an upper limit of $2\times10^{-12}\,\mathrm{cm^2\,s^{-1}}$. For Fe-Mg interdiffusion in Ca-rich pyroxene, only Sanford and Huebner's¹6 calculated minimum value of $4\times10\,\mathrm{cm^2\,s^{-1}}$ at 1,050 °C is available. Sneeringer and Hart¹7 obtained a diffusion coefficient for Sr in diopside of $2.7\times10^{-12}\,\mathrm{cm^2\,s^{-1}}$ in the range 1,250-1,300 °C. None of these values is very well established, but they seem to suggest that there are no significant differences between the rate of re-equilibration of major elements and Sr. One may thus speculate that, for a given mineral couple, Sr isotopes are equilibrated only if the major elements have also reached equilibrium.

Therefore, we conclude that pyroxene geotherms or similar features have no simple interpretation. More probably, the (P, T) determination corresponds to fossil conditions, but different rocks have recorded these conditions at different times.

If the minerals in the sheared nodules form an internal isochron of age T_1 relative to a parent-daughter system, the P-T conditions calculated for the minerals correspond to the time T_1 . If this were indeed the case, it would call for a process in which high-temperature equilibrium was frozen and preserved for a long time. Hofmann and Hart¹⁸ stated that "subcontinental lithosphere is essentially protected against high temperatures and reworking by virtue of the overlying crust" and the xenoliths could come from mantle levels where the temperature has long been below the closure temperature for diffusion of the major elements as well as Sr.

Figure 1a is an isochron diagram showing the diopside-garnet joins for sheared xenoliths from the Thaba-Putsoa pipe. Note that these tie lines intersect each other almost at a unique point. Furthermore, the steeper the slope of the tie-lines, the lower the 87Sr/86Sr ratios for the diopside. We consider this as a strong evidence against impurity effects, particularly on garnet separates, as we expect that random impurity effects would yield random intersections of the tie lines. Thus, we would closely approximate the ideal situation depicted in Fig. 1b in which the system is re-equilibrated isochemically at different times $(T_1, T_2, \text{ and so on})$. The fact that diopside and garnet practically account for the total content in Rb and Sr of the garnet lherzolites supports our hypothesis. An important geochemical implication is that the sheared xenoliths from Thaba Putsoa represent various portions of a mantle system with a common Rb/Sr ratio, the value of which is quite low. The fact that the sheared-lherzolite mineral phase (and thus the whole rocks) show a remarkable coherence relative to some trace elements¹ is consistent with our speculation.

The situation illustrated in Fig. 1b may be readily converted into another linear relationship by plotting slopes against intercepts. Because Fig. 1 is an isochron diagram, the slopes rep-

resent times and the intercepts, the initial ⁸⁷Sr/⁸⁶Sr ratios and hence the Sr isotopic characteristics of this particular mantle system can be further examined in terms of its Sr isotopic evolution. Figure 2 shows a good linear fit, not only for the four sheared xenoliths from Thaba Putsoa but also for a sample from the Premier Mine pipe (1,400-Myr old kimberlite).

Compared with the bulk earth Sr isotope evolution curve, the sheared xenoliths define a Sr isotopic evolution for a depleted mantle; this evolution trend is very similar to that for the oceanic lithosphere¹⁹. If we calculate the $^{87}\text{Rb}/^{86}\text{Sr}$ ratio for the uncontaminated whole rocks, through the isotopic evolution diagram (Fig. 1b), we get values around 0.05, which undoubtedly indicates a depletion since the bulk earth value is 0.09.

The Sr isotopic characteristics summarized above may be interpreted in terms of continuous or episodic thermal accretion of the continental lithosphere at its base. When an old shield continuously accretes this lithosphere the earliest fraction producing the uppermost lithospheric mantle is derived from older mantle which, until that time, has been undepleted; the youngest fraction producing the lower part of the continental lithosphere shows the reverse trend.

In contrast, we can admit that continental lithosphere was mostly created just after the local orogenic processes which built the local continental crust. The subsequent cooling of such episodic accreting lithosphere is not uniform with depth. Therefore, the isotopic freezing occurs at different times for different depths, creating the observed isotopic zonation.

In either model, we must consider independently the granular xenolith data. These samples are depleted in major elements but some are quite undepleted in terms of their ⁸⁷Sr/⁸⁶Sr ratios. The characteristics of these xenoliths may be explained through a two-stage model. At their depth level, melting occurred,

creating some continental basalts such as the Karroo basalts. The granular facies would thus represent residues after basalt extraction events which are indeed quite recent. However, some of the granular samples correspond to higher level and they have a ⁸⁷Sr/⁸⁶Sr signature quite undepleted, others correspond to a lower level and are more depleted. Such volcanism extracted basalts, leaving residual material such as the granular-facies rocks, yield fluids which induced mantle metasomatism. The combination of the two phenomena created the complexities in the chemistry and isotopic characteristics of the continental lithosphere.

We thank J. C. Mercier, S. R. Hart, and B. Dupré for helpful discussions. This is I.P.G.P. contribution NS/571.

Origin of longitudinal triangular ripples on the Nova Scotian continental rise

Brian E. Tucholke

Woods Hole Oceanographic Institution, Woods Hole, Massachusetts 02543, USA

Since the recognition of current-produced bedforms in the deep ocean, attempts have been made to predict direction, intensity and variability of abyssal flow from the nature of sea floor irregularities (see refs 1-3). Longitudinal triangular ripples (LTRs) are intermediate-scale bedforms (<20 cm high, metres long) that are becoming recognized as important and geographically widespread predictors of bottom-current flow. I describe here recent sea floor photographs of LTR fields on the lower continental rise off Nova Scotia which show that the bedforms develop in fine-grained, cohesive sediment with an alignment parallel to the regional contours and to mean current direction. An observational model for LTR formation is proposed, wherein LTRs are deposited initially as 'tails' behind large sea floor biological mounds and are subsequently constructed and propagate in the direction of mean current by sediment transport oblique to the bedform axis. This transport is induced by short-term currents that deviate from mean current direction and cause formation of a separation bubble on one side or the other of the LTR crest.

Current-produced bedforms in the deep ocean range from mere lineations a few millimetres high to abyssal sediment waves up to 100 m high and several kilometres in wavelength. Among the larger bedforms that can be photographed with conventional deep-sea cameras are LTRs ranging up to ~15 cm high, 1 m wide and several metres in length. Such features appear to align with the mean current direction, and they have been photographed at depths of 4,600-5,400 m along the lower continental rise off eastern North America⁵⁻⁷, at the foot of the Bahama Banks⁸, on the north-east Bermuda Rise⁹, and in the

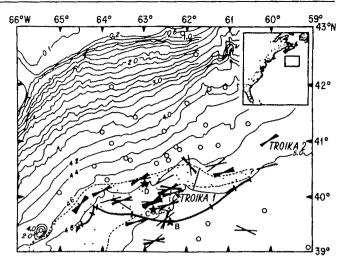

Fig. 1 Location and orientation of longitudinal triangular ripples¹⁶. Note that even NW-SE oriented LTRs at right centre parallel local bathymetric contours. Troika-1 was a 3.4-km photographic transect and Troika-2 an 8.1-km transect. O, Photograph stations with no LTRs. Surface sediment in stippled area contains more than 10% sand. Bathymetry in corrected metres. *, Locations of current-meter records ¹⁴: B, 15-day record; C, 215-day; D, 230-day; progressive vector diagram at B is tick-marked at 2-day intervals.

south-west Indian Ocean¹⁰. Recent detailed sea floor investigations for the high energy benthic boundary layer experiments (HEBBLE)¹¹ have shown that LTRs are widespread at depths of 4,700-5,100 m on the lower continental rise off Nova Scotia (Fig. 1). The bedforms have been photographed with both a Ewing-Thorndike bottom-bounce camera 12 (high-angle oblique view) and a Troika camera sled¹³ (low-angle oblique view).

The LTRs on the Nova Scotian continental rise are best developed at depths of 4,800-5,000 m. The surface sediment is a sandy silty clay (<20% sand, 30-50% silt and 30-60% clay). LTRs tend to be better developed and more frequent on the southwestern part of the continental rise where sediments also have higher sand content (Fig. 1). They generally align within 10°-15° of the strike of the bathymetric contours. Individual LTRs are up to 15 cm high, about 1-5 m long, and their spacing ranges from <1 m to several tens of metres (Fig. 2). Width ranges up to ~1 m and varies roughly in proportion to height. The ripples are mostly bilaterally symmetrical, and they are occasionally slightly sinuous. Ripple-crest height is not constant but varies by a few centimetres along the length of a ripple (Fig. 2e). Where the tails (downstream, south-west ends) of the LTRs are observed, they blend smoothly into the sea floor. In contrast, the heads of the LTRs merge smoothly with the sea floor in only about one-third of the ripples. The remaining ripples have a distinct bulge at the head, often recognized as a biologically produced mound (Fig. 2b, d). Thus it seems that the LTRs commonly, if not ubiquitously, have formed behind such obstacles to flow.

Associated with the LTRs are various other current-produced bedforms. Most common are fine lineations a few millimetres high, and crag-and-tail features up to 1 cm high and several centimetres long; these often occur on the LTRs (Fig. 2). Orientation of these smaller features is more irregular than that of larger bedforms, suggesting that there is significant shortterm (days to weeks?) variability in the direction of currents that produce the small-scale bedforms. Measured currents in this area do show such variability superimposed on a mean contour-parallel flow towards the south-west¹⁴. The LTRs themselves appear to be 'vector-averaging current vanes' oriented in the direction of long-term mean flow.

The small-scale bedform patterns superimposed on the LTRs are pertinent to LTR origin. Close study of photographs shows three kinds of ripple-crest development. Least common is a sharp, symmetrical crest: more often the crest is rounded

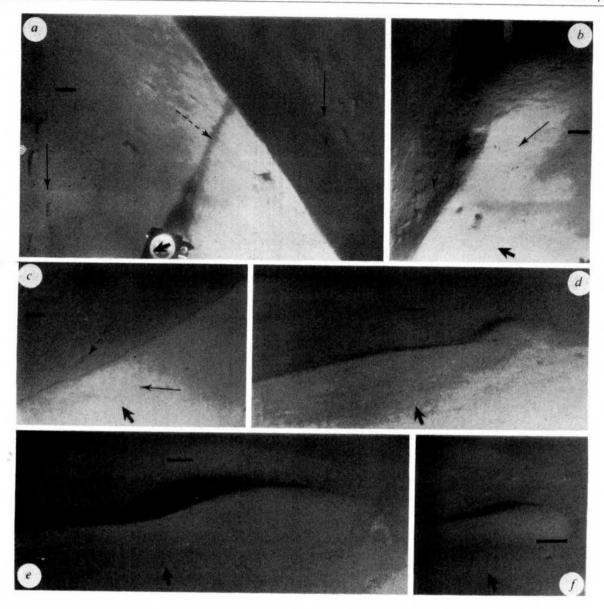

Fig. 2 Photographs of longitudinal triangular ripples. Bold arrow shows true north. a, LTR showing southwesterly flow within separation bubble on north flank (dashed arrow); main flow is to west (solid arrow). b, LTR formed behind biological mound; arrows as in a. c, LTR with cornice forming ripple crest. d, LTR developed behind biological mound. e, Mound at head of LTR, possibly of biological origin and current-modified; in d and e, changes in ripple-crest height give false appearance of sinuosity. f, Biological mound with well-developed tail, possibly precursor to LTR. a, b, and c are high-angle oblique photographs (courtesy C. D. Hollister); c, d, and e are low-angle oblique Troika photographs. Scale bars, 10 cm.

(Fig. 2d). In both cases fine current-produced lineations usually parallel the ripple crest. A third, common situation is a slightly asymmetrical crest (Fig. 2a, c). In such instances the fine-scale lineations define a short-term current trending at an angle to the crest (usually <45°), and a small 'slip-face' or cornice can be developed on the lee edge of the crest (Fig. 2c). On the lee flank of the ripple, the fine-scale lineations also trend upwards towards the ripple crest. The lee-side lineations indicate a zone of flow convergence; this convergence is thought to occur in a separation bubble because farther downstream from the ripple the lineations again parallel those on the upstream flank (Figs 2a, 3). Laboratory experiments by Allen (ref. 15, pages 210-216) show similar formation of a separation bubble behind skewed straight steps in a flume bed. When the incident current is at <40°-45° to the step (ripple) an open separation bubble is formed; it has helical internal flow (Fig. 3) that can extend beyond the tail of the ripple. A closed bubble, having internal circulation but lacking the extended helical flow, forms at greater angles of incidence (45°-135°).

Based on these observations, I propose that longitudinal triangular ripples originate as a consequence of four factors: (1) presence of a large (~10-20 cm high) seabed obstacle to flow; (2) bedload transport and/or deposition from suspended load; (3) presence of bottom currents with a significant mean flow; and (4) definite variation in direction of flow about the mean. In this model an obstacle to flow, such as a biologically produced mound, creates a leeward zone of flow convergence (wake); a tail oriented in the direction of mean flow is deposited in this wake. Common observation in beach and dune areas shows that beneath directionally uniform flows such a tail reaches only a finite size determined by the length of the wake behind the obstacle. However, where significant variations in flow direction occur, I suggest that a separation bubble is formed on one side or the other of the initial tail in response to the cross-bedform flow (Figs 2a, 3). The tail (ripple) thus is further constructed by bedload and/or suspended load transport towards the bedform crest on both sides of the ripple. This occurs in both closed- and open-bubble situations (any angle

of current incidence)15. However, at angles of current incidence <40°-45° an open separation bubble having helical flow should extend beyond the end of the bedform and facilitate elongation of the LTR through convergent bedload transport. As the LTRs propagate, the original flow obstacle may be modified and eventually be removed by erosion. As with the original moundand-tail, the LTRs parallel mean flow direction.

Of the four factors requisite to this model, the presence of a significant mean flow and superimposed variability are reasonably well documented from bottom photographs 16 and current measurements¹⁴. Current measurements at 5,022 m within the LTR area (Fig. 1) show a mean velocity of 28 cm s⁻¹ towards 253°, nearly parallel to the regional contours (~245°) over a 15-day period. Currents vary a total of about 110° in direction (190°-300°); for current speeds in excess of 50 cm s⁻¹, the total variation is about 60° (240°-300°). Longer-term records at 4,950 m (215 days) and 4,770 m (230 days) have considerably more variation in direction and lower maximum speeds (<40 cm s⁻¹), but they still show a significant mean velocity of 7-8 cm s⁻¹ directed towards about 250° (ref. 14).

The degree to which ripple construction results from bedload or suspended load transport is unclear. Bedload transport is suggested by better development of LTRs in the slightly coarser sediment on the south-west part of the Nova Scotian rise, but the texture and the LTR development could be independent responses to the particular current regime in this area. Asmechanism whereby suspended sediment is 'plastered' onto the bedform cannot be ruled out. Finally, the requirement for the presence of a flow obstacle to initiate LTR formation is supported by numerous photographs showing biological mounds at the head of LTRs as well as in varying states of elongation by currents (Fig. 2). I cannot absolutely define any of the time scales involved, but in light of the variability recorded in current measurements it is reasonable to suppose that the ripples take at least months to years to form beneath the mean flow and that the short-term variations (and small-scale lineations) occur over periods of days to weeks.

This model contrasts with one proposed by Flood⁷ for LTRs in the Blake-Bahama Basin. He suggested that LTRs may form by very rapid deposition beneath short-lived, high-velocity current events. This explanation is unlikely for the Nova Scotian continental rise because such current events commonly are not oriented parallel to the contours (deviations up to 55°, ref. 14) while the LTRs almost always are parallel. Furthermore, photographs from the Nova Scotian rise show that many LTRs consist of highly consolidated mud, often gouged at oblique angles by tool marks made by large bedload-transported particles. If the LTRs were evanescent bedforms, it is doubtful that they would achieve such strong consolidation. In the Blake-Bahama Basin, numerous biologically produced mounds of scale similar to the LTRs are observed in Flood's photographs, and the bedforms therefore may have an origin similar to those on the Nova Scotian rise.

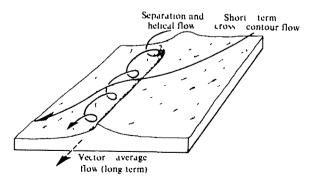

Fig. 3 Sketch showing propogation of LTR in direction of mean flow behind a biological mound. Instantaneous current oblique (<45°) to LTR and to mean flow stimulates helical circulation in separation bubble at left side of LTR. Alternations in current direction shift separation bubble between left and right sides of LTR, and they average to the long-term mean flow.

The qualitative model I have proposed does not deal with a host of important subtleties (such as the distribution of bed shear stress) in the nature of interaction between the boundarylayer flow and the bedforms. However, it presents a working hypothesis that agrees with available data and that can be tested by the future HEBBLE experiments and in laboratory conditions. The model predicts that longitudinal triangular ripples are characteristic of a specific set of flow conditions, namely significant short-term variability superimposed on a welldefined and geologically significant mean flow. Such conditions are most likely to be met on low regional slopes where deep boundary currents are established, especially along the western margins of ocean basins.

Drifting buoy trajectories in the North Atlantic Current

W. Krauss & J. Meincke

Institut für Meereskunde, University of Kiel, D 2300 Kiel 1, FRG

Despite intensive research, there are still large gaps in our knowledge of the North Atlantic Current which is considered to be the link between the Gulf Stream off the east coast of North America and the anomalously warm surface waters off northwestern Europe. In the classical scheme given in Fig. 1, which was constructed by Dietrich1 on the basis of data obtained during 1957-58, the current is seen to comprise several branches. Two important difficulties arise from this interpretation. First, the data for the area east of Newfoundland are not sufficient to define the causes of why the branching of the North Atlantic Current is stationary in its source area over the slope off Grand Banks2. Second, rapid surveys of the oceanic temperature structure by means of expendable sondes and, increasingly, of long-term moored instrumentation and satellitetracked drifting buoys3 have revealed that the oceanic current field is dominated by mesoscale eddies and meanders rather than by large-scale steady flows. We report here two experiments using satellite-tracked buoys which address these difficulties. Our results clarify the pathway of the North Atlantic Current and confirm that the current indeed consists of mesoscale eddies and meanders.

7

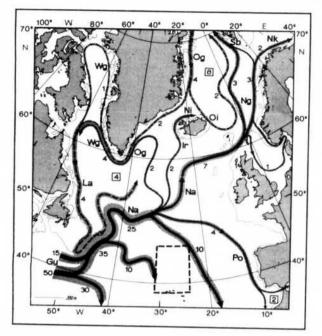

Fig. 1 The branching of the North Atlantic Current (Na) as inferred from the hydrographical data obtained during the International Geophysical Year 1957–58 (see refs 1, 2). The numbers indicate transports in the layer 0–1,000 m, given in $10^6 \, \mathrm{m}^3 \, \mathrm{s}^{-1}$. The dashed box depicts the area shown in Fig. 4.

In summer 1981, we carried out two experiments. The first was designed to verify the branching of the North Atlantic Current east of Newfoundland. Ten satellite-tracked buovs with drogues at 10 m depth were deployed by the Canadian RV Baffin between 5-8 and 14-16 May 1981 along two lines normal to the strong frontal zone south-east of Grand Banks. The lines were about 130 km apart. The buoys were launched at about 50 km intervals along these lines, starting in the zone of major horizontal gradients and running out into warm water. According to Fig. 1, this deployment would be predicted to release the buoys into the waters of the 'central' branch turning towards the Azores, into the 'northern' branch deviating into the southern Labrador Sea before crossing the Mid-Atlantic Ridge near 52° N and into the region of the anticyclonic gyre, located, according to Mann4 and Fig. 1, between the central branch and the Gulf Stream termination area.

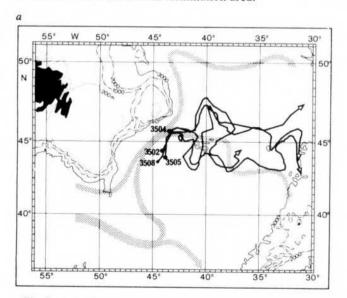

Figure 2a shows the trajectories of two groups of buoys. Drifters 3509 and 3507 were released at 12.2 and 10.0 °C sea-surface temperature in the most northwestern positions of the two launching lines. Both of them followed the northern branch of the North Atlantic Current; Buoy 3507 was trapped by the Flemish Cap for about 3 months before continuing northwards. The second group consisted of drifters 3500, 3501. 3503 and 3506, which were released at the most southeastern ends of the two launching lines at temperatures of 15.5, 16.5, 16.0 and 16.5 °C respectively. Buoy 3506 failed after a few weeks, while the other three drifters remained stagnant in the gyre area and could not escape until at least mid-September. The trajectories of a third group are shown in Fig. 2b. It includes buoys 3502, 3504, 3505 and 3508, which were deployed between the two groups shown in Fig. 2a at water temperatures of 15.3, 14.7, 16.5 and 16.8 °C respectively. All four buoys entered the central branch, and on nearing the Gauss Seamount group, two of them passed it to the north and two to the south. They continued to meander towards the Mid-Atlantic Ridge.

It is clear from Fig. 2a, b that the amplitudes of meandering and eddying are large enough for the trajectories of the different groups of drifters to overlap. For example, at around 2 June drifters 3504 and 3508 passed through the 'stagnation' area on their southern paths around the Gauss Seamounts; they had thus crossed the trajectory of drifter 3501 65 days earlier and would cross that of drifter 3500 8 days later. Drifter 3501 cut across the 1957-58 position of the current branch and the related front south-east of the Grand Banks without any significant change in the surface temperature readings. Sixty days later it also cut across the trajectories of the four drifters that finally followed the central branch. The existence of branches and a gyre (or stagnation area), as indicated in Fig. 2a, b, would suggest at least 200 km of spatial variability in the pathway of the current. A preliminary analysis suggests that wind did not significantly affect the trajectories during the observation period. First, the drogue-load sensors that were operational indicated no losses of drogues during the experiment. Second, winds were generally weak and variable during the first 2 months and even when they increased over the area between 30° and 50°W and 40° and 50°N from the south-west for two extended periods in late July and August, they did not cause a uniform displacement of the buoy field.

A few studies of the meandering and eddying of drifting buoys in the western³ and eastern⁵ Atlantic have provided evidence for a relationship between buoy trajectories and individual hydrographical features like Gulf Stream meanders or eddies and rings. We have now investigated this relationship

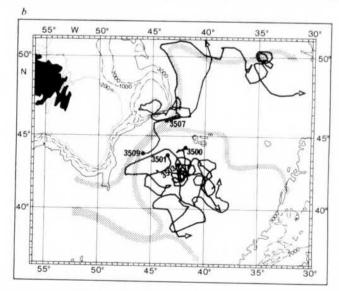

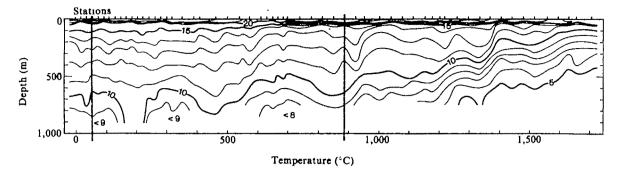

Fig. 2 a, b, Five-month trajectories of drifters drogued at 10 m depth and released mid-May 1981. The start of the trajectories is denoted by a dot and the number of the drifting buoy. The stippled areas correspond to the current branches shown in Fig. 1. Depths exceeding 3,000 m not contoured.

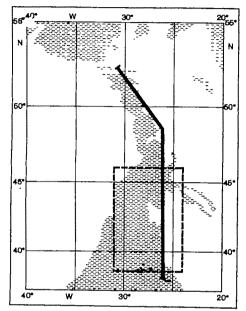

Fig. 3 Temperature section along the eastern flank of the Mid-Atlantic Ridge north of the Azores obtained on 12–16 August 1981. The portion of the section between the dashed lines corresponds to the meridional extent of Fig. 4. The small map shows locations in relation to the Mid-Atlantic Ridge (stippled area).

for a 700×400 km area over the Mid-Atlantic Ridge north of the Azores in August and September 1981. Figure 1 shows the location of this area between the northern and the central branch of the North Atlantic Current. A three-dimensional survey of the temperature and salinity fields was carried out at the same time as nine drifters drogued at 30 and 100 m depth were followed. The hydrographical setting in Fig. 3 shows the area to be dominated by mesoscale features. It also indicates that the drogues of the drifters were reaching down through the surface mixed layer. Figure 4 displays the depth of the 10 °C isotherm, which is representative of the depth of the main thermocline. It is based on 363 XBT and 49 CTD stations with an 'average' spacing of ~20 km. Four cold and three warm eddies have been found with an average diameter of 150 km. The trajectories of the buoys superimposed in Fig. 4 indicate a geostrophic flow around the eddies as a first approximation. The close correlation between the trajectories from the uppermost layers and the hydrographical structure at the depth of the main thermocline indicates that the eddy field dominates the flow in the warm water sphere. This result is confirmed by current meter records obtained by a moored vertical array. The current shear observed in the depth range from below the mixed layer to 662 m depth corresponds to that expected from the horizontal temperature gradients shown in Fig. 3.

It took 25 days to complete the hydrographical survey, including a repeat survey of the central and the northeastern region of the area shown in Fig. 4. As the trajectories presented in Fig. 4 are for a period 9 days longer, the eddy field must constitute a quasi-synoptic distribution. This is a basic requirement for most of the further analysis to be performed on this data set.

Another set of drifting buoys was released in August 1981 over the Mid-Atlantic Ridge between 46° N and Gibbs Fracture Zone at 52° N. It seems from the paths that an eddy field similar

to the one presented in Fig. 4 covers all this area. The buoys are still drifting across the North Atlantic and are expected to arrive off the the European coasts in spring 1982.

Drogued drifters provide a useful tool with which to investigate the kinematics of the current system, especially if simultaneous surveys of the hydrographical structures are possible. The extent to which satellite monitoring of sea-surface temperature pattern can help interpretation of buoy trajectories is not yet clear. IR satellite images of the region shown in Fig. 4 do not reveal any eddy field for the southern and the eastern

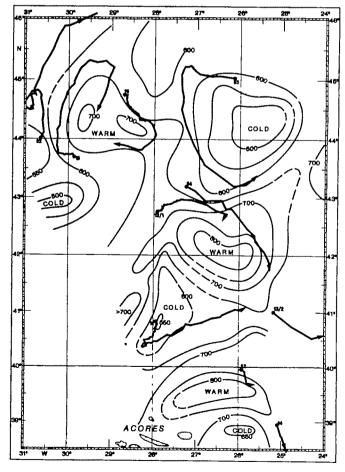

Fig. 4 The topography of the 10 °C isotherms and the trajectories of drifters drogued at 30 and 100 m depth. The start of the trajectories is denoted by a dot and the number of the drifter. The hydrographic survey lasted from 12 August to 6 September 1981. The trajectories are shown for the period 12 August to 15 September, with the exception of drifters 14 and 52, which started on 5 September. For general location of the area see Figs 1, 3.

part of the study area, although some features can be identified in the northwestern part.

Cooperation and competition within coalitions of male lions: kin selection or game theory?

Craig Packer & Anne E. Pusey

Allee Laboratory of Animal Behavior, 5712 South Ingleside, Chicago, Illinois 60637, USA

Male lions form cooperative coalitions which compete against other coalitions for exclusive access to female groups^{1,2}. This cooperation and the apparently low level of intra-coalition competition over oestrous females, have been considered to be due to the close genetic relatedness of the males in the coalition¹⁻⁴. However, we now present evidence that breeding coalitions of male lions include non-relatives much more commonly than was generally supposed, that intra-coalition competition over females is widespread and that kinship is not the primary factor determining levels of competition.

Between July 1978 and May 1981 we studied the population of lions in the Serengeti, Tanzania, described by Schaller⁵, and all the lions resident on the floor of Ngorongoro Crater. Lion prides are stable social groups composed of 2-18 adult females, their dependent offspring and a coalition of 1-7 adult males (which can simultaneously control more than one group of females). Genealogical records have been maintained since 1966 for two prides in the Serengeti⁶ and since 1974 for another 13 prides in the Serengeti and Ngorongoro². We made daily censuses of as many prides as possible and recorded the incidence of fresh wounds, the consort partners and mating activity of each male, and the presence of non-consorting males ('rivals') within 200 m of each consort pair. We collected over 500 h of behavioural data on consort pairs during 2 h watches at dawn and dusk.

Theoretical analyses of male coalitions have assumed that they are always composed of relatives^{1,2}. However, there are examples of unrelated males becoming companions² data show that 42% of breeding coalitions of known origins

Table 1 The composition and origins of the 20 male coalitions having tenure in prides in the Serengeti and Ngorongoro during 1978-81

Coalition sizes	Origins
6, 5, 5, 4, 3, 2, 2 3 7, 4, 4, 4, 3 3, 2 3, 2, 2, 2	Unknown Pair of unknown origins with son Cohort from same natal pride Full siblings All unrelated Sibling pair with unrelated third

Males were considered relatives if they came from the same natal pride or joined their probable fathers, and non-relatives if they were known not to have come from the same natal pride or if they had associated with a variety of male partners for over a year before coming together (consistent with the behaviour of males known to be from different prides and completely unlike that of males of the same natal pride).

contained non-relatives (Table 1). This proportion is higher than the 10% reported by Bygott et al.2, because their data included cohorts that had not yet gained a pride (J. D. Bygott, personal communication). There is considerable mortality among subadult and nomadic males so that by the time they gain a pride their initial companions may have been lost and new ones found.

Competition for individual oestrous females between males from the same coalition consists primarily of competition for temporary 'ownership' of the female. When a female in a pride comes into oestrus, the first male that encounters her forms a consortship with her and this 'confers temporary dominance on the consorting male '5,6. The consorting male maintains proximity (usually <1 m) to the female, herds her and prevents other males of his coalition from moving too close to her. Behavioural oestrus (days with mating) lasts about 4 days. during which time copulation occurs once every 25 min; the inter-oestrus interval is about 16 days7. The male sometimes guards the female for 1 or 2 days before mating and for up to 6 days after mating has ceased. Males occasionally 'mistake' a potentially oestrous female, guarding her for a day or two and then leaving her after she fails to come into oestrus.

As both coalitions containing relatives and those containing non-relatives were common, it was possible to determine whether kinship affected intra-coalition aggression over oestrous females. Threats without contact by consorting males towards other males were common and occurred mainly when the other males were within 15 m of the consorting male's female (84%, n = 63 threats). Most of these threats (53%) were the direct result of the female attempting to move closer to rivals (or other consorting males). Kinship had no effect on the frequency of threats by consorting males to rivals (calculated per minute spent by a rival within 15 m of a consorted female and based on six consorting males whose unrelated companion(s) spent any time within 15 m of his consort partner, and on 12 males whose related companion(s) spent time within 15 m; U = 36, P > 0.50), or the time spent by rivals within 15 m of the consorted female (based on 10 males who had unrelated consorting companions, and 19 males who had related consorting companions; U = 76, P > 0.20). The fact that rivals spent any time as close as 15 m to the consort pair was due primarily to the behaviour of the female. Their presence at more moderate distances, however, depended on the behaviour of the rival, and rivals were more likely to be within 200 m of a consorted oestrous female as the availability of other possibly oestrous females declined (Fig. 1).

More serious intra-group fights over females included slapping and biting and frequently resulted in wounding of one or both males. Such fights were observed nine times and could be inferred another five times from fresh wounds on one or both males together with a change of consort partners. Serious fights were no more common between non-relatives than between relatives (P > 0.50); rather, they were context specific: of 13 fights where the context was known or could be inferred, eight occurred when 'ownership' of the female was undecided or unclear and four involved two consorting males. Ownership was 'undecided' when two males simultaneously came into the vicinity of an unconsorted, potentially oestrous female; and was 'unclear' when the consorting male moved further from the female than was the rival. There was usually a race between males to arrive first at a female. On arrival, the loser would defer to the winner though in subsequent consortships the previous consorting male might be a rival to the new consorting male (also see ref. 5). Lion males can consort simultaneously with two females and females being consorted by different males occasionally tried to come into close proximity to each other. In such cases one consorting male sometimes tried to take over the other's female.

Males also competed in a less direct manner to be the owner of a female when she came into oestrus. Males guarded nonoestrous females, probably in anticipation of the female's oestrus, and this was most common when the availability of oestrous females was lowest. When only one female in a pride was being consorted, the consorting male was more likely merely to be guarding a non-oestrous female than on days when several females were being consorted (T=40, n=19 males) observed consorting at least twice in each condition, P<0.05).

Males in Ngorongoro Crater guarded non-oestrous females more frequently than did males in the Serengeti. When only one female was consorted, the female was not in oestrus on 80% of occasions in the Crater (based on the behaviour of 11 consorting males) but on only 42% of occasions in the Serengeti (n = 24, U = 69, P < 0.025). Guarding of non-oestrous females may be more common in the Crater because it is less costly. Consort pairs rarely hunt and therefore feed infrequently⁵, but prey density in the Crater is so high and pride ranges so small⁸ that consort pairs can more easily join pride mates at kills.

Because fights over oestrous females are so rarely observed, males of a coalition have been said to 'share' females and to do so because they are relatives (see refs 1, 2). However, two factors should be taken into account when attempting to measure differential reproductive success among males of a coalition. First, females in a pride tend to come into oestrus at the same time^{5,6}. In our study, on the first day of 43% of oestrous periods other females in the pride were also in oestrus (n = 150). Second, females tend to move to additional mating partners after their first mating partner loses interest in them at the end of oestrus⁷. Subsequent partners show only a brief interest in the female and females seek additional partners most often when their fertility is lowest7. Thus calculating the relative mating activity of males without controlling for either the number of females in oestrus or the order in which males consorted with a particular female (as in refs 1, 2) biases against finding any differences in reproductive success.

The extent of differential male reproductive success was measured in 11 coalitions using data that eliminated these biases (Table 2). Coalitions consisting solely of relatives did not 'share' females more equally than did coalitions containing non-relatives. However, differences in competitive ability did result in differential male reproductive success. Disparities in consorting success were greater in coalitions in which the males were of markedly different ages or sizes than in those where all the members were evenly matched (Table 2). In all six of the former coalitions, the non-prime (either very young or old) and small individuals consorted less frequently with oestrous females than did their larger or more vigorous companions.

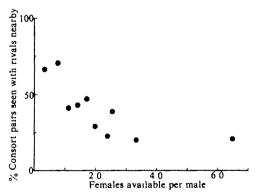

Fig. 1 The proportion of sightings (n=222) in which non-consorting males ('rivals') were seen within 200 m of consort pairs plotted as a function of the number of potentially oestrous females available to those males elsewhere (number of unconsorted females not pregnant or with cubs/number of non-consorting males). Only data taken from coalitions which had sole control of a pride are used and points were taken at least 4 days apart. Eight of nine coalitions showed trends similar to the overall result (P < 0.04) and there was no difference between the Serengeti and Ngorongoro, so all data were pooled and cells combined to give a $k \times r$ matrix with sufficient sample size to test for heterogeneity $(\chi^2 = 23.87, 9 \text{ d.f.}, P < 0.01)$. The trend for rivals to be present more often when fewer females are available elsewhere is significant $(r_s = 0.89, n = 10, P < 0.01)$.

Table 2 Extent of differential mating success in each coalition

Mating success of respective males	Includes non-relatives?	All same age and size?	I_{T}
3, 0, 0	Unknown	No	2.00
3, 0, 0	Unknown	No	2.00
5, 5, 0, 0, 0	Unknown	No	1.50
4,0	Yes	No	1.00
2, 0	Yes	No	1.00
3, 3, 0, 0	Unknown	No	1.00
7, 4, 3, 2, 2, 1, 1	No	Yes	0.47
7, 4, 2, 2	No	Yes	0.30
3, 2, 1	No	Yes	0.17
2, 1, 1	Yes	Yes.	0.13
2, 2	Yes	Yes	0

Each line gives data on a different male coalition. For each male in each coalition, the number of oestrous periods is given in which he consorted with a female who was the only oestrous female available to that coalition on the day when she was first observed mating. Only the first male to mate with the female in each of these periods is considered, unless a male was seen to win the female from another male in a fight-in these cases the victor was also included. Only coalitions in which the average number of such periods is one or more per male are included. For each coalition a measure of differential mating success, I_T (ref. 14), was calculated. Large values of I_T indicate unequal mating success; smaller values indicate evenly distributed mating success. Coalitions containing members of different size or age showed significantly more unequal mating success than coalitions with equally aged and sized members $(n_1 = 6, n_2 = 5, U = 0, P < 0.01)$, but there was no significant difference between coalitions consisting solely of relatives or including non-relatives $(n_1 = 3, n_2 = 4, U = 6, P > 0.50)$.

The high proportion of coalitions containing non-relatives is not surprising. Because singleton males almost never gain control of a pride and coalitions of three or more father more surviving offspring per male than do smaller coalitions², selection will favour singletons and pairs forming coalitions with additional males. As females are frequently in oestrus simultaneously, even subordinate males often have access to females.

Males would benefit even by cooperating with non-relatives but should prefer relatives as partners^{9,10}. We know of no case where a male with related companions left them for an unrelated companion, although there were cases where additional relatives were not accepted. A group of three relatives prevented three younger relatives from joining them, and incorporation of sons into the coalition was known or suspected only when the number of older males was one or two (n = 4 coalitions). In coalitions of three or more, incorporation of sons has never been seen, even though such large coalitions are more likely to maintain tenure long enough to father surviving sons² Because large coalitions can control prides without additional companions, they would be expected to exclude additional members when an added male would reduce each male's reproductive success (but not when the exclusion results in a loss in inclusive fitness). This is especially important if the new male would become disproportionately successful as in the case of ageing males being joined by males nearing their prime

Costs to males of direct competition for oestrous females can be high: one-to-one fights typical of such encounters often result in wounds to the face and eyes and sometimes in blinding⁵. Even in a gang attack on a single individual, the lone animal can wound several of its opponents. Furthermore, the loss of a companion through fighting may shorten tenure in the pride¹. Game theoretical analysis predicts that when costs of fighting are high, contests may be settled 'conventionally' through recognition of asymmetries such as 'owner versus rival' or 'large versus small', rather than through overt aggression 11-13. As differences in size or vigour exist in only about one-third of male coalitions (7 of 20), the 'respect' of ownership in lions is particularly important. Males were seen to compete for females indirectly by anticipating oestrus in a female in order to be the 'owner' when she eventually came into oestrus and they did

this more often when costs of guarding and availability of oestrous females were lowest. Fights were virtually restricted to occasions when ownership was unclear or when two consorting males were in close proximity.

In conclusion, the low levels of aggression observed within coalitions of male lions, which had been ascribed to kin selection, are not affected by the degree of genetic relatedness of the males and may be better understood in terms of game

Properties of the Ca2+-activated K+ channel in one-step inside-out vesicles from human red cell membranes

Virgilio L. Lew, Shmuel Muallem* & Carol A. Seymour

Physiological Laboratory, University of Cambridge, Cambridge CB2 3EG, UK

The presence of a calcium-activated potassium channel in some mammalian red cell membranes makes them useful experimental models in which to study the properties of similar mechanisms believed to be involved in the control of membrane potential and conductance, at rest and during activity, in many other cells. However, vesicles prepared from human red cell membranes by the method of Steck et al.1, whether inside-out (IOVs) or right-side out (ROVs), either failed to show any Ca2+-activated component of K+(Rb+) fluxes2 or showed only a very reduced calcium sensitivity and K⁺/Na⁺ selectivity³. This is surprising because there is good functional preservation of other transport mechanisms, such as the anion carrier⁴, Ca² pump⁵ and Na⁺ pump⁶. Our failure to confirm reports⁷ that the calcium response could be restored in 'silent' IOVs by addition of protein concentrates from red cell lysates prompted the search for and discovery of vesiculation procedures which produced ion-tight IOVs in a single step, with minimum loss of membrane components and transport properties⁸⁻¹¹. We report here (1) the conditions which favour preservation or loss of the Ca2+-activated component of the 86Rb efflux from one-step IOVs, (2) an approximate estimate of the number of Ca² activated K+ channels per red cell, and (3) that individual Ca²⁺-activated K⁺ channels respond in an all or nothing fashion to Ca2+ activation and differ in their threshold sensitivity to ionized calcium.

The IOVs used in these experiments were prepared by the one-step method and loaded with 86Rb+ as detailed in Fig. 1 legend. Preliminary experiments had indicated that when the one-step IOVs are resuspended in media which can sustain the activity of the Na⁺ pump (see Fig. 1 legend), the ⁸⁶Rb⁺ release caused by ATP addition exposes the total ⁸⁶Rb⁺ space sealed within IOVs that contain Na+ pumps. Figures 1 and 2 compare this Na⁺-pump IOV space with that accessible to Ca²⁺-activated channels, in conditions which optimally preserve (Fig. 1) or partially inhibit (Fig. 2) the Ca²⁺-dependent ⁸⁶Rb⁺ release.

In 11 experiments similar to that of Fig. 1, using red cells from three different donors, the ratio, r, of the 86Rb+ space accessible to Ca2+-activated channels to the 86Rb+ space accessible to Na+ pumps varied between 0.86 and 1.02. With an average of 500-1,500 vesicles of non-uniform size per cell¹¹ and 100-200 Na⁺ pumps per cell^{12,13}, the probability of a vesicle having more than one pump will be rather low. However, most of the ⁸⁶Rb⁺ released will be from the larger vesicles which contain a larger fraction of the ⁸⁶Rb⁺-sealed vesicular volume¹¹. These vesicles are more likely to have both pumps and channels, thus causing more overlap than expected had all the vesicles been of uniform size. If the surface density of pumps and channels is assumed to be uniform, the similarity of ⁸⁶Rb⁺ space accessible to Na+ pumps and K+ channels could reflect identity of the two mechanisms 14, structural linkage or simply numerical parity. The first two possibilities are unlikely because of the additional ⁸⁶Rb⁺-releasing effects of Ca²⁺ and ATP shown in Figs 1b and 3, which suggest that there are vesicles with either one or other of the two transporting systems. If the assumptions made here were correct, the number of Ca2+-sensitive K+ channels, like that of Na+ pumps 12,13, would be in the range of 100-200 per cell.

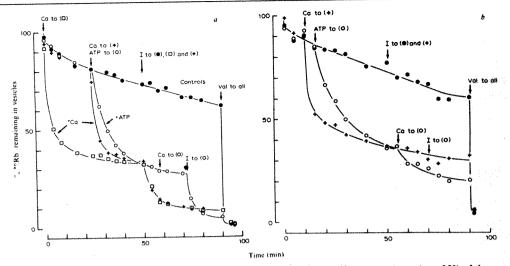

The experiment of Fig. 2 represents the conditions which cause relative channel inhibition. Lysis and vesiculation at high pH and in the presence of EDTA cause a variable reduction in r (0.06-0.65 range, in seven experiments similar to that of Fig. 2). As with the uninhibited channels (Fig. 1), the Ca2induced 86Rb+ release also saturated at about 50 µM Ca2+. Addition of concentrated protein extracts from red cell lysates or purified calmodulin15, as with Steck-type vesicles, failed to restore r and only had minute random effects. Partial inhibition, therefore, seems to represent irreversible channel inactivation. Low pH (7.5) per se had no effect on r. The critical condition for optimal channel inactivation seems to be enhanced divalent cation chelation by high pH (8.5) during vesiculation, as if the most vulnerable configuration were only transiently present at this stage. Higher EGTA or EDTA concentrations (0.5-3 mM) interfered with vesiculation itself and could not be tested. Used before or after, but not during, vesiculation, they caused only small and rather variable reductions in r even at pH 7.5, and, as before, only in the absence of added Ca²⁺ or Mg²⁺. These inhibitory effects of EGTA or EDTA at high pH could perhaps explain the failure to observe Ca2+-activated components of the K⁺(Rb⁺) fluxes in some of the Steck-type vesicle preparations2.

The protective effect of Ca²⁺ and Mg²⁺ suggests an interesting alternative interpretation of the Ca²⁺-sensitivity curves reported in resealed ghosts containing buffered calcium¹⁶⁻¹⁸. It may be that part of the reported Ca²⁺ affinity for activation of the channel represents Ca²⁺ affinity for protection against irreversible inhibition by EGTA. This interpretation is supported by preliminary experiments with resealed ghosts containing 1 mM EGTA and ⁸⁶Rb⁺. The Ca²⁺-dependent ⁸⁶Rb⁺ release was inhibited by up to 80% when Ca²⁺ was incorporated using the ionophore A23187 only during a final incubation relative to ghosts sealed from the beginning with similar buffered Ca2+ concentrations.

In 'one-step' IOVs, with partial or total preservation of functional Ca²⁺-sensitive K⁺ channels not able to be inhibited further, the true Ca2+ sensitivity of the K+ channels may be studied directly. As shown in Fig. 3, the striking finding was that with increasing Ca2+ concentrations, progressively more

Fig. 1 Effects of ATP and Ca2+ on the Rb+ release from one-step human red cell IOVs. Red cells from freshly drawn blood were washed four times in about 8 vols of isotonic media containing NaCl+KCl, 150 mM, and Tris-Cl (pH 7.8 at room temperature), 10 mM, packed to about 80% haematocrit and lysed in 40 vols of an ice-cold medium containing Na-HEPES (pH 7.5), 2.5 mM, and Na-EGTA, 0.1 mM. After about 10 min, to allow for completion of lysis, 40-ml aliquots of this suspension were centrifuged for 10 min at 30,000g in the cold (4°C), the ghost pellets resuspended in 2-4 ml of the same lysing medium and incubated at 37 °C for 60 min. Spontaneous insideout vesiculation occurs during the first 15-20 min of this incubation, as described before9, but membrane elasticity increases with time11, allowing

subsequent tragmentation and rescaling of a fraction of the vesicles by vigorous passage through 27-gauge needles. Earlier measurements of $(Ca^{2+} + Mg^{2+})ATPase^{11}$ indicated that at least 25% of the original red cell membrane area surrounds IOV-sealed vesicular space. Traces of ${}^{86}Rb^+$ (10-50 μ Ci ml⁻¹) were added before (a) or after (b) vesiculation. Addition before vesiculation secures maximum ${}^{86}Rb^+$ trapping within the resealed vesicular space; after vesiculation, incorporation of ${}^{86}Rb^+$ was by needling. The 86Rb*-loaded vesicles (from 1 ml original 'packed' cells) were washed once (to remove extravesicular tracer), and resuspended in 8-12 ml of a medium containing (mM):NaCl, 50; KCl, 10; Na-HEPES (pH 7.5), 25; MgCl₂, 1.5; EGTA, 0.02 (medium 'A'). The 86Rb* remaining in the vesicles was measured, at the indicated times after the start of the final incubation (37 °C), in 0.1-ml aliquots of this suspension, run through Tris-neutralized Dowex 50-X-8 (200-mesh) columns contained within glass-wool-plugged Pasteur pipettes and eluted with 1.5 ml of ice-cold sucrose (200 mM) directly into counting vials. The results are expressed as per cent $^{86}\text{Rb}^+$ remaining in vesicles relative to the samples at t=0. The indicated additions were taken from concentrated stock solutions expressed as per cent — RD remaining in vesicles relative to the samples at t = 0. The indicated additions were taken from concentrated stock solutions (concentration in parentheses) to give the following final concentrations (mM): Na-ATP (100 mM), 1.5; A23187 (I) (2 mM in absolute ethanol) 0.01; CaCl₂ (30 mM), 0.07; valinomycin (Val) (1 mM in ethanol) 0.001. The final Ca²⁺ concentration of 0.05 mM used here elicited maximal ⁸⁶Rb⁺ release in all conditions (not shown). The average vesicle diameter was ~0.2 μ m. Addition of ionophore A23187 in the presence of Ca²⁺ revealed a substantial ⁸⁶Rb⁺ space contained within ROVs (a). This compartment did not incorporate much tracer by needling (b). Establishing the proportions of ROVs to IOVs by assaying acetylcholinesterase activity as in multistep vesicles, does not give reliable values in one-step IOVs because vesiculation is performed without washing and the enzyme may easily reassociate with both sides of the membrane. Ca²⁺ addition after ATP-induced ⁸⁶Rb⁺ depletion had no measurable effect in a but caused further ⁸⁶Rb⁺ loss in b. In a, where all the resealed vesicular space was labelled, a disproportionate fraction of this space may be contained within the larger vesicles. Their chance of having more than one pump or channel may be higher than in the smaller labelled vesicles of b and this may explain the larger overlap of *6Rb* space

available to both mechanisms without necessarily postulating identity or link (see text).

vesicles released their 86Rb+ at the same maximum relative rate, instead of, as expected, all the channel-containing vesicles releasing their 86Rb+ at increasingly higher rates. The ratio between the rate measured over the first 5 min and the steadystate difference remained virtually constant at all Ca2+ concentrations (see Fig. 3 inset).

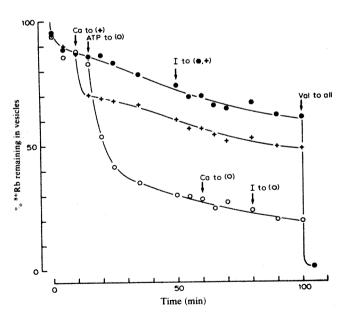

Fig. 2 Inhibition of Ca2+-induced relative to ATP-induced 86Rb+ release in one-step human red cell IOVs. This experiment was identical to that in Fig. 1a except that lysis and vesiculation were performed in a medium containing (mM): Na-HEPES (pH 8.5), 2.5, and Na-EDTA, 0.1. Possible inhibition of the Ca-sensitive channels in the ROVs could explain the failure of A23187 to activate further 86Rb+release as in Fig. 1a. In any case, the contaminant ROV space in this experiment cannot exceed 22% of the total **Rb*-resealed vesicular space because at least 78% of it must be contained within IOVs with Na+ pumps.

This means that Ca2+ activation is all or nothing for each channel and that the channels differ in their threshold Ca2+ sensitivity. The insert in Fig. 3, therefore, does not report any true or apparent Ca2+ affinity, but the distribution of Ca2+ thresholds in the channel population of this vesicle preparation. In three other similar experiments, there was some variation in the threshold distribution curve, with channels still being activated in the 2-10 µM Ca2+ range, but always in an all or

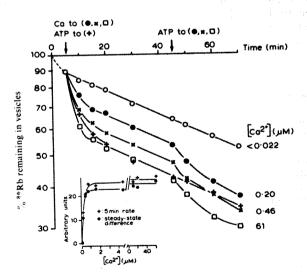

Fig. 3 Ca²⁺-sensitive ⁸⁶Rb⁺ loss from one-step IOVs as a function of the concentration. IOVs were prepared as in the experiment of Fig. 1a. The final suspending medium ('A') had a contaminant Ca²⁺ concentration (as determined with Ca²⁺ electrodes) of 7 and 100 µM of added EGTA. CaCl₂ was added to give the calculated concentrations of Ca²⁺ shown. ATP addition as in the experiment of Fig. 1. In three other experiments using medium A and 1 mM EGTA, the threshold distribution curve (see inset) was shifted slightly to the right (app $K_1 = 2 \mu M$). Ca²⁺ uptake by the IOVs before ATP addition was less than 2% of the total Ca²⁺ even at the lowest Ca2+ concentration (not shown). This rules out Ca2+ depletion through vesicle binding as the possible cause of the all or nothing response.

nothing fashion. Apparent changes in Ca2+ sensitivity therefore result from shifts in the threshold distribution curve.

If the all or nothing response of each channel reflects the behaviour of the channels in the original cells, a graded increase in K⁺(Rb⁺) flux in intact cells or resealed ghosts, in conditions where the Ca²⁺ concentration is uniformly raised in all the cells, must reflect either activation of only a fraction of the channels in each cell or, if all the channels belonging to the same cell had similar Ca²⁺ thresholds, activation of all the channels in only a fraction of the cells. It is unlikely that cells with few or no channels contribute to the graded response because, when Ca²⁺ is incorporated at high ionophore (A23187) concentrations in intact cells, the entire cell K⁺ pool participates in the ⁴²K⁺-tracer equilibration process¹⁹. Tracer K⁺(Rb⁺) pools retained within cells with inactive channels have been observed

in intact cells and resealed ghosts²⁰⁻²⁴, although seldom in conditions of known uniformity of Ca²⁺ or Pb²⁺ (ref. 20) content. Such all or none cell responses^{20,24}, however, do not imply all or nothing single channel behaviour as found here, because they can also result from variations in the Ca2+ sensitivity of channels belonging to different cells, each channel responding to Ca²⁺ in a graded manner.

Too little precise information exists at present to define the range of possible kinetic models which could explain the present observations. Sharp all or nothing responses at a molecular level may require interacting configurational changes, occluded states or dCa2+/dt-sensitive gating mechanisms.

All-or-none response of the Ca²⁺-dependent K⁺ channel in inside-out vesicles

Javier García-Sancho, Ana Sanchez & Benito Herreros

Departamento de Fisiología y Bioquímica, Facultad de Medicina, Valladolid-5, Spain

In several cell lines, an increase in the intracellular Ca2+ concentration elicits an increase in the membrane permeability to K⁺(Rb⁺) by activation of the so-called Ca²⁺-dependent K⁻ channel. The human red cell has been widely used to study this transport system². As Ca²⁺ (refs 3, 4) and other possible modulators^{5,6} act on the intracellular side of the membrane, a preparation of everted vesicles would be most useful for investigating such actions. Although several previous studies in inside-out vesicles have been unsatisfactory 8-10, a new vesiculation procedure that preserves Ca^{2+} -dependent K^+ transport has recently been reported 11,12. Using this preparation we now find that each vesicle responds to Ca2+ in an all-or-none fashion, the number of activated (permeable to ⁸⁶Rb) vesicles increasing with Ca2+ concentration between 10-8 and 10-6 M. This behaviour probably reflects the all-or-none response of individual K^+ channel units. The sensitivity to Ca^{2+} is decreased by Mg2+

⁸⁶Rb fluxes were measured at room temperature and in equilibrium exchange conditions. In vesicles loaded with ⁸⁶Rb during the vesiculation step, the addition of Ca²⁺ to the medium elicited a rapid release of ⁸⁶Rb, the efflux rate constant returning close to control values (without Ca²⁺) after 10-20 min. The fraction of vesicular space emptied of ⁸⁶Rb during this rapid phase increased in a graded stepwise fashion with increasing Ca²⁺ concentrations, being maximal at 10⁻⁴ M (Fig. 1a). A similar behaviour was observed for the uptake of ⁸⁶Rb (Fig. 1b). Both the transient nature of these rapid 86Rb fluxes and the graded response suggest that increasing Ca2+ concentrations activate an increasing number of vesicles, each vesicle responding in an all or nothing fashion with a fast and full equilibration of ⁸⁶Rb. Time-dependent inactivation of the K⁺ channel was excluded because vesicles loaded with ⁸⁶Rb by a 15-min incubation in the presence of submaximal concentrations of Ca2+ released most of their radioactivity when transferred to tracerfree medium containing the same Ca2+ concentration. On the other hand, if the vesicles were loaded at a Ca2+ concentration giving maximal response (10⁻⁴ M) and then transferred to medium containing different submaximal Ca2+ concentrations, there was a graded stepwise release similar to that shown in Fig. 1.

The simplest explanation for the graded vesicular response is that the different vesicles have different threshold sensitivities to Ca²⁺. However, the same response would be expected for a vesicle population of uniform sensitivity responding at random if the state of each unit (active or inactive) cannot change as long as the Ca2+ concentration remains unmodified. A kinetic model that could explain the all or nothing response of the K+ channel has been proposed by Lew, Muallem and Seymour (see accompanying letter¹³).

Our measurements of the space resealed to 86Rb after vesiculation show that each red cell should provide 200-300 vesicles. Assuming that the number of K⁺ channels per cell is less than 200 (ref. 12), the mean frequency of channels per vesicle should be below 1. In agreement with this prediction, we find that a substantial fraction (15-40%) of ⁸⁶Rb loaded during the vesiculation step is not released by Ca²⁺, even in the presence of the ionophore A23187, which renders right-side out vesicles sensitive to Ca2+. It thus seems reasonable to assume that most of the Ca2+-sensitive vesicles should have only one or a few channel units. On these bases, the all-or-none nature of the vesicular response does probably reflect the behaviour of individual channel units.

The Ca²⁺-induced fluxes were specific for Rb (²²Na fluxes remained unchanged) and sensitive to quinine (92-97% inhibition at 1 mM) at Ca²⁺ concentrations ≤ 10⁻⁶ M, properties similar to those described in intact cells or resealed ghosts3,14-18. However, at 10^{-4} M Ca²⁺, we found a quinine-insensitive increase of the fluxes of ²²Na (to twice the basal value) and ⁸⁶Rb (see the difference between the values at pCa 4 and pCa 6 in Fig. 2). This observation suggests a nonspecific effect of Ca2+ at such concentrations and is reminiscent of the simultaneous increases of Na+ and K+ permeabilities reported previously in red cells after treatments that presumably increase their intracellular Ca2+ content19

The study of the kinetics of the Ca²⁺-induced ⁸⁶Rb fluxes was complicated by their rapidity $(t_{1/2})$ of ~ 0.5 min) and also by the fact that they could not be described by single exponentials. However, the fraction of the vesicular space equilibrated with the incubation medium at the end of the rapid phase for a given Ca²⁺ concentration was highly reproducible between experiments if expressed as the per cent of the maximal effect. In addition, these values were similar for the uptake and release experiments. The activation of ⁸⁶Rb fluxes began at 10⁻⁸ M Ca²⁻¹ and was almost complete at 10⁻⁶ M Ca²⁺, half-maximal activation occurring at a pCa of ~ 7.55 (Fig. 2).

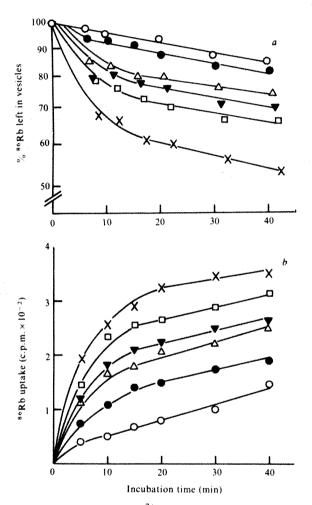

Fig. 1 Effects of external Ca^{2+} on the release (a) and uptake (b) of ⁸⁶Rb by inside-out vesicles. Vesicles prepared as described by Lew and Seymour ¹² were needled, washed once and resuspended in medium of the following composition (mM): KCl, 18; EGTA, 0.1; K-HEPES, 16.5, pH 7.5. For the transport experiments, 0.2-ml aliquots of vesicle suspension (corresponding to ~ 0.2 g of initial cells) were mixed with 0.6-1 ml of medium. 86Rb was added either to the vesiculation medium (release experiments) or to the final incubation medium (uptake experiments). Fixed Ca² centrations were obtained using mixtures of EGTA or Nhydroxyethylethylenediamine triacetic acid (HEDTA) (final concentration 0.4 mM) and calcium. Dissociation constants, measured in the incubation medium²⁰, were: EGTA, 4×10^{-8} ; HEDTA, 4×10^{-7} . The incubation period was terminated by running 0.1-ml aliquots of the vesicle suspension through 1-ml columns containing Dowex 50-X8-100 resin 12.21. Radioactivity was measured by Cerenkov counting. Symbols represent the following pCa values: ≤9 (○), 7.85 (●), 7.55 (△), 7.37 (▼), 6.88 (□), 4.00 (×). Vesicular space resealed to ⁸⁶Rb (ref. 12) ranged over 76–130 μ l per g of cells in different experiments. 40-70% of that space was sensitive and this value increased to 60-85% in the presence of 2 μM A23187. Everted vesicular surface was 25-35% of the total.

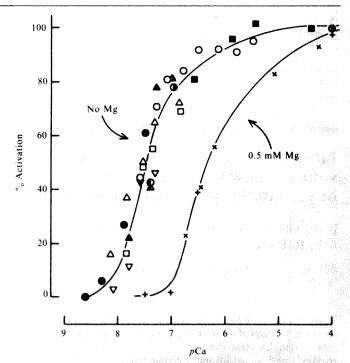

Fig. 2 Activation of ⁸⁶Rb transport by Ca²⁺. The vesicular space sensitive to Ca²⁺ (that which equilibrates with the medium during the rapid phase) was calculated from experiments similar to those shown in Fig. 1 by extrapolation to zero-time. Per cent activation was then calculated taking the value obtained without Ca2+ as 0% and that obtained at pCa 4 as 100%. The results obtained in 14 experiments with vesicles prepared using different blood samples are shown with different symbols. Squares represent data obtained in release experiments while all other symbols correspond to uptake experiments. The curve on the left was obtained in the absence of Mg^{2+} and the one on the right with 0.5 mM Mg^{2+} .

The procedure described here offers an easy way of investigating modifications of the sensitivity to Ca2+ of 86Rb transport. The addition of 5×10⁻⁴ M MgCl₂ to the medium reduced the apparent pCa value at which half-maximal activation of ⁸⁶Rb transport took place (pCa_{1/2}) from 7.55 to 6.35 (Fig. 2). Smaller Mg²⁺ concentrations $(2 \times 10^{-5}, 5 \times 10^{-5}, 10^{-4}, 2 \times 10^{-4} \text{ M})$ produced smaller variations of pCa_{1/2} (7.35, 7.15, 6.95, 6.82), a 10-fold increase of Mg²⁺ concentration decreasing pCa_{1/2} by 0.58 units. The inhibition of Ca²⁺-dependent K transport by Mg²⁺ reported here is consistent with previous observations in resealed ghosts¹⁵. The actions of other intracellular effectors on the sensitivity to Ca2+ of K+(Rb+) transport could be investigated similarly. Experiments performed in our laboratory have shown, for example, that neither calmodulin nor NADH modifies the kinetics of activation by Ca2+ nor the inhibition by Mg²⁺ or quinine. Work is now in progress to investigate the effects of other intracellular proteins and reducing agents.

We thank Dr V. L. Lew for valuable discussions and J. Alvarez for technical assistance. This study was supported in part by a grant from the Fondo Nacional para el Desarrollo de la Investigación Científica.

Intracellular Ca2+activates a fast voltage-sensitive K+ current in vertebrate sympathetic neurones

P. R. Adams*, A. Constanti†, D. A. Brown† & R. B. Clark

Department of Physiology and Biophysics, University of Texas, Medical Branch, Galveston, Texas 77550, USA

Many neurones, when depolarized, exhibit two components of outward K+ current—the voltage-sensitive delayed rectifier current originally described in squid axons by Hodgkin and Huxley¹, and an additional current triggered by the entry of Ca^{2+} ions². These two currents have been termed I_K and I_C , respectively³. Previous experiments have indicated that both forms of K^+ current are also present in vertebrate sympathetic neurones⁴⁻⁶. We have now studied the properties of $I_{\rm C}$ in bullfrog sympathetic neurones, uncontaminated with I_{K} , by injecting Ca2+ ions into the cells and measuring the resultant outward currents under voltage-clamp, in the manner previously used for large molluscan neurones^{7,8}. We find three interesting properties of $I_{\rm C}$ in these vertebrate neurones. First, it shows strong voltage sensitivity independent of the voltage sensitivity of the Ca2+ channels (which have been bypassed by the injection technique). Second, I_C activates and deactivates very rapidly ($\tau_c \le 20 \text{ ms}$ at 0 mV), with stepped changes in membrane potential. Current fluctuation analysis and patchclamp records of single-channel currents yielded evidence for appropriate short-lifetime ionic channels with a maximum conductance of $\sim 100 \text{ pS}$. Finally I_{C} in ganglion cells is highly sensitive to external tetraethylammonium. We deduce that in these neurones I_C is a fast current which can contribute a substantial fraction to the repolarizing current during an action

Figure 1a illustrates outward currents evoked in a voltageclamped bullfrog sympathetic neurone by brief iontophoretic intracellular injections of Ca2+ ions at different holding potentials. The first two panels show currents produced by equal negative and positive iontophoretic pulses at the initial holding potential of -30 mV. There is no change in current-to-ground (upper trace) during the negative iontophoretic pulse because the iontophoretic current was balanced by positive clamp current and no additional active membrane current was induced. However, during positive iontophoresis an unbalanced outward membrane current appears, outlasting the iontophoretic injection. With such brief (<1 s) iontophoretic applications, repeatable currents could be recorded at 5-10-s intervals without decrement. At any given holding potential the peak outward current increased linearly with increasing iontophoretic currents up to 10 nC. However, the sensitivity varied greatly from cell to cell: it was usually within the range 1-3 nA outward current per nC injected current at -30 mV, but some cells showed no response to 10 nC or more. Assuming a transport number of 0.3 for Ca^{2+} in 0.2 M $CaCl_2$ solution, 10 nC current should expel ~1.5×10⁻¹⁴ mol of Ca^{2+} ion; in a spherical cell of

 \sim 40 µm diameter this is equivalent to an increment of \sim 0.5 mM internal [Ca²⁺], although the increase in free ionized [Ca²⁺] is presumably much less because of buffering and redistribution. Unlike the situation in large molluscan neurones⁷, vertical movement of the iontophoretic pipette did not greatly alter the magnitude or time course of the current response, suggesting that in the smaller ganglion cells the intracellular Ca2+ concentration very rapidly attained homogeneity. Control injections to ± 10 nC from electrodes filled with 0.3 M KCl at pH 5.8 did not produce outward membrane currents.

The outward current generated by constant iontophoretic Ca²⁺ injections increased steeply as the membrane was depolarized between -50 and -20 mV, as shown on the right of Fig. 1a. In normal Ringer solution the current fell to zero around -50 mV and did not reverse with further hyperpolarization. Clear reversal to an inward current (at -35 ± 2 mV (\pm s.e.m.); n = 8) was obtained on raising [K⁺]_{out} to 25 mM. Assuming the underlying conductance change G_c at any membrane potential to be unaffected by raising [K⁺]_{out}, the hypothetical reversal potential in normal Ringer solution (containing 2.5 mM K⁺) could be calculated from the ratio of the currents evoked at a fixed holding potential in normal and high [K+] solutions and from the reversal potential in high [K⁺]. The mean extrapolated reversal potential in normal Ringer was estimated at -78± 7 mV (n = 5), and the positive shift on raising [K⁺] 10-fold was $+41 \pm 7 \, \text{mV}$.

At a reversal potential of -78 mV, the voltage dependence of $I_{\rm C}$ shown in Fig. 1a accorded with an exponential increase in the underlying conductance ($\Delta G_{\rm C}$) for each 7.5 mV depolarization above -50 mV. In seven experiments of this type, the average slope was 11 mV per e-fold $\Delta G_{\rm C}$ up to -10 mV. This is appreciably steeper than that previously reported (25 mV (ref. 8) and 28 mV (ref. 10)) for the voltage-sensitivity of $I_{\rm C}$ activated by intracellular Ca²⁺ injections in molluscan neurones. Removal of external Ca²⁺ or addition of the Ca²⁺-channel blocker Cd²⁺ in concentrations (0.2-0.5 mM) sufficient to block the inward Ca2+ current in bullfrog sympathetic neurones11 did not materially change this voltage sensitivity, showing that it was related solely to the action of internal Ca²⁺ and not to any inward Ca²⁺ current. Steady outward currents at depolarized potentials were reduced in Cd2+ solution, which allowed the membrane potential to be held at more positive potentials than in normal Ringer solution. This revealed that, at potentials positive to $-10 \,\mathrm{mV}$, I_{C} tended to saturate and, in some cells, actually diminished with increasing depolarization. This could not be alleviated by reducing the iontophoretic Ca2+ current.

When a voltage step was applied during a Ca²⁺ injection, the outward current showed an exponential growth or decline with time, and a time constant of ~15 ms at -10 mV command potential (Fig. 2a). To study these relaxations in more detail, the single microelectrode clamp method (which had limited current-passing capacity) was replaced with a conventional twoelectrode clamp⁹ and I_C was generated either by Ca^{2+} injection or by activating a sustained inward Ca²⁺ current with a long depolarizing command. Figure 3 shows examples of such depolarizing commands, in another context. During sustained depolarization the delayed rectifier current becomes totally inactivated so that, if no Ca²⁺ is present in the external solution, only a leak current is recorded and a superimposed voltage step produces a square 'ohmic' current response (Fig. 2b, lefthand record). When Ca2+ is added to the external solution the inward Ca^{2+} current generates an additional outward I_C (which is blocked by Cd2+) and a voltage step now produces a timedependent relaxation comparable with that seen during a Ca2+ injection (Fig. 2b, right panel). The average time constant for this relaxation (τ_c) was 16.0 ± 0.9 ms (n = 10) at -10 mV. Over the range -80 to +30 mV, τ_o showed an exponential lengthening for each 27 mV depolarization. An equivalent voltage sensitivity of these relaxations was confirmed when Ca²⁺ was injected through a third intracellular microelectrode.

The current record during long depolarizations in Ca²⁺ solution was distinctly 'noisy'. This noise disappeared on removing

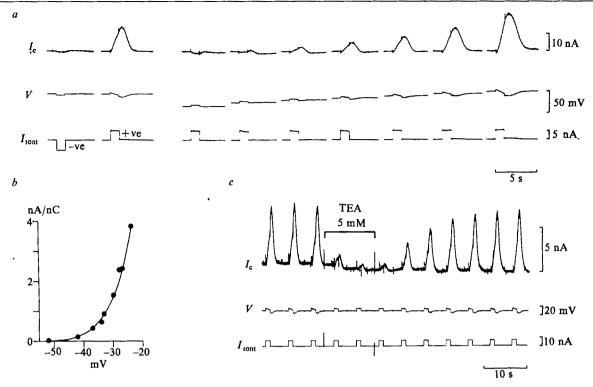

Fig. 1 Outward currents generated by intracellular Ca²⁺ injections in voltage-clamped bullfrog sympathetic neurones. Lumbar sympathetic neurones were maintained at 22 °C in normal Ringer solution containing 2.5 mM KCl, 2 mM CaCl₂, 10 mM MgCl₂ and 2 mM Tris buffered to pH 7.2 with HCl. Neurones were impaled with two electrodes drawn from thin-walled glass tubing (tip resistances 8-20 MΩ). One electrode, filled with 0.2 or 0.4 M CaCl₂ solution in distilled water (pH 5.8), was used to record membrane potential and to inject clamp current via a sample-and-hold voltage-clamp preamplifier (Dagan 8100, switching between voltage sampling and current injection at 3 kHz). Clamp current (upper trace m a and c, I_C) was recorded as true current-to-ground, filtered at 300 Hz; iontophoretic current (lower trace in a and c, I_{Cm}) was recorded by subtracting Dagan current (continuous output) from current-to-ground. The records in a show responses to 1 s, 6 nA iontophoretic injections of Ca²⁺ at different membrane holding potentials between -55 and -20 mV, preceded by test responses to negative and positive iontophoretic currents at -30 mV holding potential b, Shows the change in peak outward current with holding potential. The potential on the abscissa is the recorded membrane potential at the height of the current response. The smooth curve shows how the current would change if the underlying conductance increased e-fold for 7.5 mV depolarization and holding potential of -30 mV.

external Ca2+ or adding Cd2+. Spectral analysis of the Ca2+dependent noise during the latter stages of the depolarization (when the a.c. current record was flat) yielded Lorentzian power spectra (Fig. 3b); spectra obtained at rest, during hyperpolarizing commands or during depolarizations in the absence of Ca2+ or presence of Cd²⁺, always resembled the background spectrum shown in Fig. 3b. The average corner frequency (f_c) of the Lorentzian spectra at a command potential of -10 mV was 7.9 ± 1.5 Hz (mean \pm s.e.m.; n = 6). This corresponds to a time constant ($\tau = 1/2\pi f_c$) of 20 ms (16.9–24.9 ms), which is similar to that for the current relaxation following a voltage jump to -10 mV. Assuming the fluctuations to arise from transient openings and closings of many individual ionic channels, each with a fixed conductance (see below), the average single-channel current can be estimated from the ratio of the total variance to the mean current¹². Total variance was calculated from the area under the test spectrum between 0.1 and 200 Hz, after subtraction of the background spectrum. The average value of the macroscopic current was taken as the median value during the spectral computation—a reasonable approximation for long depolarizations and near-linearly decaying currents. Mean Ic was determined by subtracting the current during equal but opposite hyperpolarizations, or during depolarization in the presence of Cd²⁺ or absence of Ca²⁺. (Residual currents were rather small, and imprecision in the measurement of mean $I_{\rm C}$ contributed greatly to the scatter on the resultant ratios.) In one cell clamped to 0, +10 and +20 mV, the variance increased linearly with the mean current. This suggests that the probability of channel opening was relatively low, so that the non-stationary currents would not introduce significant distortion into the spectra if analysis is restricted to the period when the a.c. current record is flat¹³, as in our experiments. The mean ratio of variance to mean I_C was 8.1 ± 1.7 pA (mean \pm s.e.m.; n = 17 cells), giving

~ .Z

an average single-channel conductance of $\sim 100 \pm 20$ pS at a reversal potential of -78 mV.

In ganglion cells cultured for 1-2 months in vitro 14 (which conveniently had naked cell membrane), appropriately large single channels could be detected using the gigohm-seal patchclamp technique^{15,16}. An example is shown in Fig. 4. At rest potential (around -60 mV in the unimpaled cells, judging from the better values obtained on impalement) the current record was quiescent. When the electrode was polarized, thus depolarizing the enclosed membrane patch, one or more discrete current channels appeared whose opening frequency and duration clearly increased with increasing depolarization. During weak depolarization the channels showed simple openclosed behaviour, but at depolarization ≥80 mV the open state was interrupted by brief closures. These became more frequent with increasing positivity, giving a very noisy open-state current level. Up to 100 mV depolarization the single-channel current increased linearly with applied potential, with a slope corresponding to ~100 pS open-channel conductance. Similar values were obtained in two other patches. However, at more positive potentials this linearity was lost and at ≥175 mV the peak single-channel current actually declined: such behaviour was seen in one other patch which could be polarized sufficiently. At 60 mV patch potential (~0 mV membrane potential) the mean channel open time was ~20 ms. The apparent open time increased exponentially per 22 mV depolarization up to +150 mV patch potential.

These single-channel events are clearly similar to those recently described in isolated mammalian chromaffin cells¹⁷ and cultured embryonic muscle cells¹⁸, in terms of both the large single-channel conductances and the open state flutterings. The latter may result from superimposed channel blocking¹⁶ or might relate to the vibrations between open and closed states

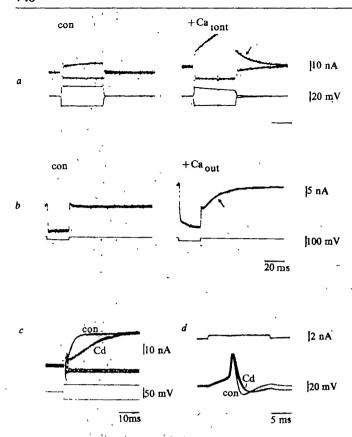

Fig. 2 Kinetic tests on $I_{\rm C}$. a, Voltage jumps of +10 mV and -10 mV applied from a holding potential of -10 mV before (con) and during (+Ca_{lout}) intracellular iontophoresis of 1 nA Ca. The single microelectrode voltage clamp technique referred to in Fig. 1 was used to record voltage and pass current: the limited current-passing capacity leads to some clamp failure during the large outward current but not during the repolarizing tail current (arrowed). b, 30 mV hyperpolarizing voltage jumps applied from a steady prepotential of -10 mV in Ca²⁺-free solution (con) and in 2 mM Ca²⁺ solution (+Ca_{out}). Two-electrode voltage clamp, no Ca²⁺ mjection. Note the relaxation (arrowed) in the presence of Ca²⁺. c, Voltage commands of ±40 mV applied from a holding potential of -50 mV in normal Ringer solution (con) and then in Ca²⁺-free solution containing 0.5 mM Cd²⁺ (Cd). Two-electrode clamp. d, Action potentials generated by depolarizing current injections in normal Ringer solution (con) and in Ringer containing 0.5 mM Cd²⁺ (Cd), recorded using independent voltage-recording and current-passing electrodes.

seen in n-acetylgramicidin channels¹⁹. As in the chromaffin cell experiments¹⁵, it was not necessary to have Ca^{2+} in the pipette to observe channels, so presumably there was sufficient free Ca^{2+} inside the cell to trigger them. Single I_C channels have also been detected in molluscan neurones²⁰, of conductance (19 pS) rather lower than but mean open times comparable with those in the ganglion cells, and in neuroblastoma cells (C. F. Stevens, personal communication).

As the cultured cells showed macroscopic C-currents of similar amplitude, time constant and voltage sensitivity to those in freshly dissected ganglia, we suppose that the single channels represent the subunits of these macroscopic currents. If this is so, the comparable duration and voltage sensitivities of the channel open times and relaxation times suggest that the latter are determined primarily by the channel closing rate. This implies that a relatively small proportion of the available channels was activated by the intracellular Ca2+ injections or by the imposed depolarizations. The fall in single-channel conductance at very positive potentials might explain the saturation of the macroscopic current with increasing depolarization. However, we also detected signs of a loss of voltage sensitivity at high internal Ca2+ concentrations. This was predicted from the observations on chromaffin cell channels¹⁷, where large or repeated Ca²⁺ injections abolished the relaxations previously generated by voltage jumps. The origin of the voltage sensitivity is not clear: voltage dependence seems too steep to be accounted for entirely by voltage-sensitive binding of Ca2+ to a site within the membrane potential field⁸, unless the binding of more than one Ca²⁺ ion per channel was necessary²¹ or an additional energy barrier were imposed²²; alternatively, voltage sensitivity might be due to the gating of the K+ channels themselves.

Two further points of interest concerning ganglionic C-channels relate to their pharmacology and physiological function. First, like some 23,24 but not all 3,25 molluscan neurones, $I_{\rm C}$ in these ganglion cells was at least as sensitive as the delayed rectifier current to external tetraethylammonium (TEA). Thus, the currents generated by ${\rm Ca}^{2^+}$ injections (Fig. 1c) or by membrane depolarization were virtually abolished by 5 mM TEA, and were half-reduced at 1 mM. In agreement with this, TEA suppressed both voltage-jump current relaxations and current noise. Thus, the effect of TEA on these neurones cannot be attributed unequivocally to inhibition of delayed rectifier currents. In contrast, $I_{\rm C}$ was insensitive to 1 mM external 4-aminopyridine.

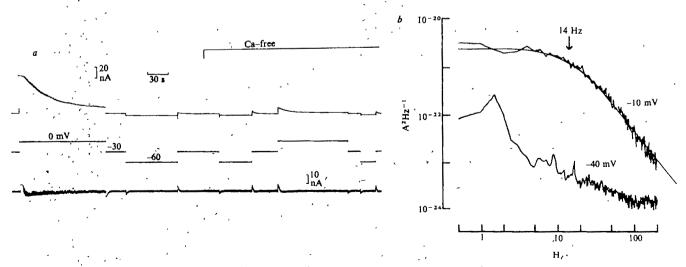

Fig. 3 Current noise associated with I_C recorded from freshly dissected ganglion cells with a two-electrode voltage clamp. The records in a show currents evoked by long ± 30 -mV commands from a holding potential of -30 mV in normal Ringer solution and after replacement with Ca^{2+} -free Ringer. Upper trace, d.c. current; middle trace, voltage; lower trace, a.c. current (0.1 Hz high-pass filter). Note that, in the absence of Ca^{2+} , the delayed rectifier current evoked by the depolarizing command subsided to a level no greater than the leak current produced by the preceding hyperpolarizing command. In the presence of Ca^{2+} there is an additional outward current showing appreciable noise. b, Power spectra of current noise (sum of 32 spectra) in another cell recorded at the holding potential (-40 mV) and during the last 64 s of a 2-min depolarizing command to -10 mV in normal Ringer solution (corrected by subtraction of the -40 mV spectrum, although this made negligible difference). The curve is drawn according to the equation $S(f) = S(0)/[1 + (f/f_0)^2]$ where S(f) is the power $S(f) = S(0)/[1 + (f/f_0)^2]$ where S(f) is the power $S(f) = S(0)/[1 + (f/f_0)^2]$ where S(f) is the power at $S(f) = S(f)/[1 + (f/f_0)^2]$ where S(f) is the power at $S(f) = S(f)/[1 + (f/f_0)^2]$ where S(f) is the power at S(f) is 14 Hz. The mean leak-corrected S(f) is the power at S(f) is the power at S(f) is 14 Hz. The mean leak-corrected S(f) is the power at S(f) is

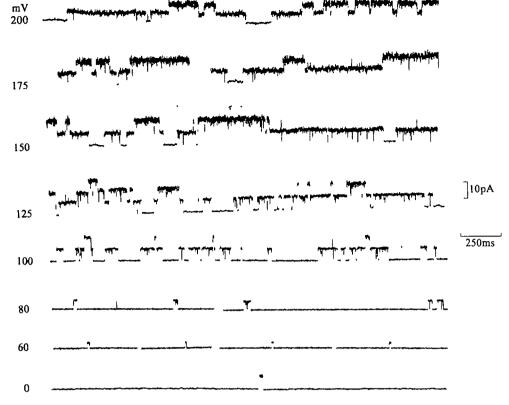

Fig. 4 Single-channel activity in a cultured bullfrog sympathetic ganglion cell. A fire-polished pipette filled with normal Ringer solution (tip resistance 3-5 M(1) was lowered vertically on to the cell membrane and suction gently applied to produce a gigohm seal. The enclosed membrane patch was initially silent but after a few minutes the electrical events illustrated in these records appeared and lasted for ~1 h. The voltages on the left show the potential of the pipette with respect to ground (thus, 0 means that the enclosed membrane patch was at rest potential, a patch potential of 60 means that the membrane patch was depolarized by 60 mV). Recording bandwidth, ~1 kHz

The second point is that, during a depolarizing voltage step following a Ca^{2+} injection, I_C develops exponentially with a time constant at least as short as that of the delayed rectifier current (which is sigmoidal and relatively slow in these neurones²⁶). Because the inward Ca²⁺ current in these cells is also fast $(\tau_{\text{max}} \sim 4 \text{ ms at } 0 \text{ mV})^{11}$, this suggests that I_C might be activated relatively early during a depolarizing event. Figure 2c shows that this is indeed the case, as addition of Ca2+ and/or removal of external Ca2+ slowed outward current development between -20 and +30 mV. Furthermore, in addition to reducing the spike after-hyperpolarization^{4,5}, Cd²⁺ clearly slowed spike repolarization (Fig. 2d). Thus, in at least a proportion of bullfrog sympathetic neurones, the K⁺ current triggered by rapid Ca²⁺ entry may subserve one of the functions more normally fulfilled by the delayed rectifier current.

Vasopressin excites hippocampal neurones

M. Mühlethaler & J. J. Dreifuss

Hypothalmic supraoptic and paraventricular neurones were the first peptidergic cells to be described in the mammalian brain¹. Most of these large nerve cells synthesize either oxytocin or vasopressin2, as well as their respective neurophysins, and project to the posterior lobe of the pituitary gland. This system of neurones is responsible for the release of these peptides into blood vessels of the posterior lobe in response to appropriate stimuli. Data obtained using immunoassay and immunocytochemical methods, however, have revealed vasopressin-like immunoreactive material^{3,4} as well as vasopressin-positive axons⁵⁻⁷ and presynaptic terminals⁵ in other central nervous system (CNS) locations. Moreover, vasopressin has been shown to affect some aspects of animal behaviour, including memory retention⁹⁻¹³. It has therefore been suggested that vasopressin may act as a neurotransmitter or neuromodulator at synapses in the brain. We show here that low concentrations $(10^{-8} -$ 10⁻⁶ M) of vasopressin powerfully and reversibly increase the rate of firing of neurones in the CA1 area of hippocampal slices from rat and that this effect can be fully antagonized by an anti-vasopressor vasopressin analogue. Hippocampal neurones obtained from Brattleboro rats were also excited by exogenous vasopressin.

We prepared transverse slices from the ventral hippocampus of male rats (~250 g body weight), as vasopressin-positive nerve fibres detected by immunocytochemical methods have been shown to terminate on the dendritic tree of pyramidal neurones

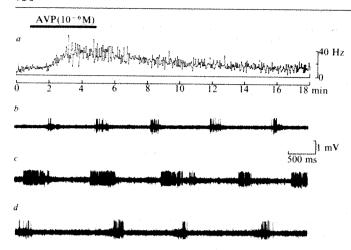

Fig. 1 Effect of vasopressin (AVP, 10^{-6} M) on the rate of firing of a CA1 neurone in a hippocampal slice. a, Ratemeter record; AVP was added to the perfusion medium during the period indicated by the thick bar. b-d, Oscilloscope tracings showing extracellular records (electrode filled with NaCl, 4 M; tip resistance, 5-10 M Ω) of the activity of the same cell before (b), during (c) and after (d) application of AVP.

in the ventral hippocampus^{5,6,14}. Slices (~500 µm thick), were laid on a nylon grid at the interface of a perfusion solution (composition (mM): NaCl 124.0; KCl 5.0; NaHCO₃ 26.0; MgSO₄ 1.4; CaCl₂ 1.0; KH₂PO₄ 1.24; glucose 10.0; temperature 37 °C) and an humidified, oxygenated (95% O2, 5% CO₂) gas mixture. A glass micropipette was lowered under visual guidance into the pyramidal cell layer in the CA1 area of the hippocampus. Substances tested included argininevasopressin (AVP; Bachem or Vega), lysine-vasopressin (LVP; Bachem, Sandoz or Serva), 1-desamino-D-arginine-vasopressin (DDAVP; Ferring), desglycinamide-arginine-vasopressin (DGAVP; Organon), oxytocin (Bachem) and the vasopressor antagonist [1- $(\beta$ -mercapto- β , β -cyclopentamethylpropionic acid)2-(O-methyl)tyrosine]arginine-vasopressin (Peninsula). These compounds were dissolved in the bathing solution immediately before application and perifused at a rate of 2.0 ml min⁻¹. Extracellular recordings were obtained in 43 slices from cells which displayed short intermittent bursts of activity in control solution.

AVP and LVP induced a sustained increase in firing rate in 56 of 63 of these cells and prolonged the duration of the bursts without markedly altering the inter-burst intervals (Fig. 1). The threshold concentration of vasopressin which accelerated cell firing was $\sim 10^{-8}$ M (Fig. 2). Maximal stimulation with AVP occurred at $\sim 10^{-6}$ M and resulted in an increase in mean firing rate from 13.5 ± 1.1 to 44.0 ± 3.2 spikes per s (mean \pm s.e.m., n=47). These concentrations of vasopressin are much lower than those required for the stimulant action of acetylcholine or glutamate ($\sim 10^{-3}$ M), but similar to those at which enkephalin excited hippocampal pyramidal neurones 15.16

The stimulatory effect of vasopressin was slowly reversible and little or no tachyphylaxis was apparent on repeated vasopressin application. We therefore attempted to compare the magnitude of the response with that produced by natural or synthetic analogues. The other mammalian neurohypophysial peptide, oxytocin, which differs from AVP and LVP in amino acid positions 3 and 8 of the molecule, excited hippocampal neurones as effectively as vasopressin in 5 of 6 cells. In contrast, DGAVP, which lacks the glycinamide terminal present in position 9, failed to excite hippocampal neurones (n = 6), even when applied at 10^{-5} M, and glycinamide $(5 \times 10^{-4}$ M) alone had no effect on cell firing (n = 3). DGAVP essentially lacks endocrine activity, but has been reported to exert an effect similar to that of vasopressin on memory and learning 17 .

Brattleboro rats, which are incapable of vasopressin biosynthesis, show behavioural deficits which can be alleviated by injecting vasopressin¹⁸. To determine whether these rats possess

in their CNS the same binding sites for neurohypophysial peptides as normal non-diabetic rats, we compared the effects of exogenous vasopressin on cells in hippocampal slices obtained from Long-Evans rats (n=8) and from homozygous Brattleboro rats (n=7). In the latter, 10^{-7} M vasopressin accelerated neuronal firing and 10^{-6} M did so more powerfully. Doseresponse relationships did not differ significantly between the two strains. As in normal rats, the stimulatory effect of vasopressin was reversibly abolished by the synthetic vasopressin antagonist.

To determine the site of action of vasopressin, small regions (~1 mm² surface area) of the CA1 area were cut from hippocampal slices. Vasopressin was as effective in these trimmed slices as in normal slices. Two further sets of experiments suggested that vasopressin can act postsynaptically. First, vasopressin was applied to slices in which the neurones had been synaptically uncoupled by raising the external Mg²+ concentration to 10 mM. The cells were no longer spontaneously active, but in 4 of 6 cells, they were still excited by 10⁻⁶ M AVP. Second, the stimulatory effect of vasopressin was not reduced by applying antagonists to various suspected transmitters. Thus neither atropine, nor propranolol nor naloxone, interfered with the action of vasopressin.

At least two types of peripheral vasopressin receptor have been recognized. The renal receptor (V2-receptor) is responsible for the antidiuresis induced by vasopressin and is linked to an adenylate cyclase 19,20. The V₁-receptor, which is not coupled to an adenylate cyclase, is present on smooth muscle cells and liver cells21,22 and triggers the vasopressor and glycogenolytic effects of vasopressin on these tissues. The availability of rather selective V2-agonists allowed the testing of the nature of the hippocampal response. DDAVP has virtually no effect on the V₁-receptor but is a powerful antidiuretic compound; in contrast, AVP and LVP exert both effects equally²³. In all four cells examined, DDAVP had a much weaker action on hippocampal cell firing than the same concentration of either AVP or LVP. Further evidence that the effects of vasopressin on hippocampal neurones were unlikely to be mediated by V_2 -like receptors was obtained from application of a V_1 -antagonist²⁴. This compound alone, at 10^{-6} M, had no effect, but

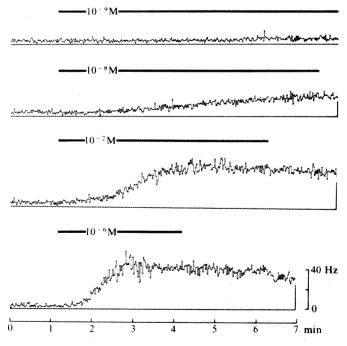

Fig. 2 Segments of ratemeter records illustrating the effects of increasing concentrations of AVP applied to the bath on the rate of firing of a hippocampal neurone, recorded extracellularly. Duration of application (solid black line) and molar concentrations are indicated above each trace.

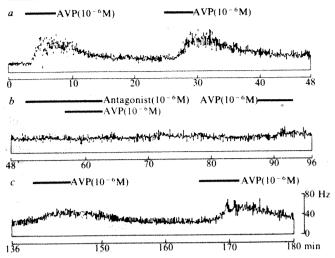

Fig. 3 Effect of the vasopressor antagonistic AVP analogue on the spontaneous and AVP-induced firing of a CA1 hippocampal neurone. Extracellular recording. AVP (10⁻⁶ M), applied at intervals of ~25 min, caused a marked increase in the rate of firing of this cell without showing any evidence of tachyphylaxis (a). The antagonist (10⁻⁶ M) did not affect firing per se, but blocked the effect of AVP for a prolonged period (b); its effect was rapid in onset, but slowly reversible (c). Note that 40 min of record have been deleted between b and c. Peptides were applied during the periods indicated by the thick black lines.

totally and reversibly abolished the effect of vasopressin on cell firing in all five cells tested (Fig. 3).

In invertebrate ganglia, vasopressin (10⁻⁹-10⁻⁷ M) induced or prolonged the burst of pacemaker neurones^{25,26}. In the rat brain, iontophoretically applied vasopressin decreased the rate of firing of cells recorded from the hypothalamic supraoptic nucleus²⁷ and increased neural firing in the locus coeruleus² In the present study, AVP and certain related peptides have been shown to increase the firing rate of hippocampal neurones when added to the medium at concentrations $>10^{-9}$ M. This threshold concentration is at least 50 times higher than the concentration of vasopressin found in cerebrospinal fluid (CSF)²⁹. Even though some peptide degradation by proteolysis may have occurred in the slices and the real concentration at the site where the effects of vasopressin arose is therefore unknown, it seems unlikely that the effect of vasopressin in the hippocampus in situ is mediated by the CSF. We interpret the results as evidence that vasopressin can act as a transmitter or modulator in the mammalian hippocampus. Indeed, other investigators have reported that cells of the CA1 region of the hippocampus are stimulated by several peptides, including enkephalins^{15,16} and somatostatin, vasoactive intestinal peptide, bombesin and CCK-8S (refs 30, 31).

Numerous data have suggested an involvement of vasopressin in facilitation of memory storage and retrieval⁹⁻¹³. DGAVP has similar activity whereas oxytocin has the opposite effect. Here we report a different structure-activity relationship for the action of vasopressin in hippocampal slices: both vasopressin and oxytocin are powerful excitants of neural firing, while comparable concentrations of DGAVP have no effect.

Control of cyclic nucleotide metabolism by non-cholinergic, non-adrenergic nerves in rat thyroid gland

S. T. Green*, J. Singh† & O. H. Petersen†‡

* Department of Physiology, University of Dundee,

Dundee DD1 4HN, UK † The Physiological Laboratory, University of Liverpool, PO Box 147, Liverpool L69 3BX, UK

In addition to the well-established role of thyrotropin (TSH) in controlling metabolism and secretion of thyroid follicular cells 1-3, there is evidence to suggest nervous (cholinergic and mechanisms4-8. control Nerves immunoreactivity to vasoactive intestinal peptide (VIP) have recently been demonstrated in the thyroid gland, while exogenous VIP has been shown to elevate tissue cyclic AMP levels, increase the number of colloid droplets in follicular cells and increase thyroid hormone secretion in vivo. It was therefore suggested that VIP-containing nerves might control thyroid activity9, although a functional non-cholinergic, non-adrenergic innervation of the thyroid has not yet been demonstrated. By adopting the technique of electrical field stimulation previously used on isolated pancreatic segments¹⁰⁻¹³, we have studied cyclic nucleotide metabolism in isolated thyroid fragments and have now demonstrated directly the influence of both cholinergic and adrenergic as well as non-cholinergic, non-adrenergic nerves on thyroid cyclic AMP and cyclic GMP metabolism. In the presence of complete cholinergic and adrenergic blockade, nerve stimulation evoked complex time course changes in tissue cyclic AMP and cyclic GMP levels which could be mimicked precisely by VIP. Electrical stimulation of intrinsic thyroid nerves released, in addition to acetylcholine (ACh) and noradrenaline, a transmitter with the same action on thyroid cyclic nucleotide metabolism as VIP.

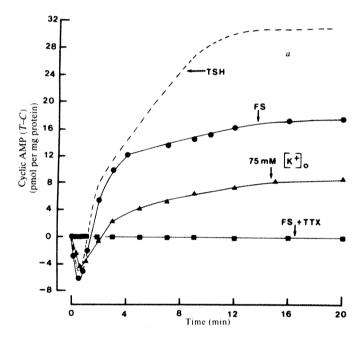

All experiments were performed on isolated fragments of rat thyroid superfused with modified Krebs-Henseleit solution, gassed with 95% O₂, 5% CO₂ and maintained at 37 °C (ref. 10). Mixed fragments (5-10 mg) of the thyroid glands from 16 rats were placed in 8 small Perspex flow chambers (vol 0.6 ml, flow 1 ml min⁻¹). Four of the chambers contained silver electrodes for electrical field stimulation (FS), the remaining four, without electrodes, served as control 'partner' preparations. The preparations (each consisting of the equivalent of two whole thyroid glands) were superfused 30 min before stimulation. At various times following onset of FS or application of drug, both

20 min	8.31	8.25	2.15	2.25

Field stimulation was continuous at 20 Hz, 50 V, with pulse durations of 1 ms. Mean (\pm s.e.) control levels of cyclic AMP and cyclic GMP were: 7.61 ± 0.29 and 2.60 ± 0.13 pmol per mg protein, respectively (n=12). The mean (\pm s.e.) levels of cyclic AMP and cyclic GMP following FS in the presence of TTX (10^{-6} M) were 7.56 ± 0.31 and 2.58 ± 0.14 pmol per mg protein, respectively (n=12). The data reveal no statistically significant difference between the test and control values (P>0.1).

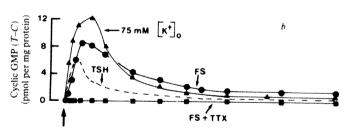

Fig. 1 Time course of changes in the concentration of cyclic AMP (a) and cyclic GMP (b) in superfused rat thyroid segments following electrical field stimulation (FS: 20 Hz frequency, 50 V amplitude, 1 ms pulse width) in the absence (\blacksquare) and presence (\blacksquare) of 10^{-6} M TTX and on exposure of preparations to Krebs solution containing 75 mM K⁺ (\triangle) . Also shown are the cyclic nucleotide concentrations in the presence of 20 mU ml⁻¹ TSH (----). Cyclic AMP and cyclic GMP in control and test frozen tissues were measured at precise time intervals after the start of stimulation using the Radiochemical Centre (Amersham) assay kits TRK 432 and TRK 500, respectively. Total protein was estimated using the Biuret method²¹ and cyclic nucleotide values expressed in pmol per mg protein. Mean $(\pm s,e.)$ control levels of cyclic AMP and cyclic GMP were 7.96 ± 0.18 and 2.38 ± 0.06 pmol per mg protein, respectively (n = 60). Each point on the graph represents the difference in cyclic nucleotide concentration between two similar preparations of thyroid segments, one serving as the test and the other as the control.

test and partner preparations (chamber plus tissue) were frozen in liquid nitrogen. Cyclic AMP and cyclic GMP in control and test frozen tissues were extracted and measured¹³.

The cyclic nucleotide concentration in a particular experimental situation was always expressed as the difference between the concentration in the test and the corresponding control preparation. Each data point in Figs 1-3 therefore represents the difference between two single measurements. The reliability of our method can perhaps best be assessed by inspection of Table 1, which shows cyclic nucleotide values in control and test preparations. Because the test in this case consisted of FS plus tetrodotoxin (TTX), that is, nerve stimulation in the presence of a blocker of nerve action potentials, we have, in effect, two parallel controls. Although there is some time fluctuation, it is clear that this occurs in parallel in the test and control preparations.

Figure 1a shows the time-course changes in tissue cyclic AMP levels during FS in the absence and presence of 10⁻⁶ M TTX and during exposure to 75 mM K⁺. The effect of 20 mU ml⁻¹ TSH is also shown for comparison. An initial, rapid, transient fall in cyclic AMP levels occurs in the first 30 s followed by a slower rise reaching almost steady state by 16-20 min. These changes in cyclic AMP concentration were abolished by superfusion of the preparation with TTX. Figure 1b shows time-course changes in tissue cyclic GMP levels during FS, on exposure to 75 mM K⁺ and during FS in the presence of 10⁻⁶ M TTX. The changes evoked by TSH are also shown. The early, rapid fall in cyclic AMP levels is accompanied by a rather slower, transient increase in cyclic GMP levels, maximal after ~1-2 min, then declining slowly, returning to the control level after 10-12 min, and remaining there throughout the stimula-

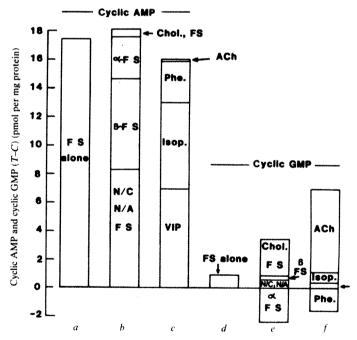

Fig. 2 Histograms showing the effects of electrical field stimulation (FS) and various agonists (for example, Phe., phenylephrine; Isop., isoprenaline; ACh, acetylcholine; and VIP, vasoactive intestinal peptide), in the absence and presence of various combinations of different blockers, on cyclic AMP (a-c) and cyclic GMP (d-f) levels (data from Table 1). a, FS in the absence of blockers. b, N/C, N/A, FS, non-cholinergic and non-adrenergic nervous component (presence of cholinergic and adrenergic blockers); β-FS, β-adrenergic nervous component (presence of cholinergic and α-adrenergic blockers and subtraction of N/C, N/A component); α-FS, α-adrenergic component (presence of cholinergic and β-adrenergic blockers and subtraction of N/C, N/A component); Chol. FS, cholinergic nervous component (presence of α- and β-adrenergic blockers and subtraction of N/C, N/A component). c, VIP (10^{-7} M); Isop. (10^{-5} M); Phe. (10^{-5} M); ACh (10^{-5} M). d, FS in the absence of blockers. e, α-FS, α-adrenergic nervous component; β-FS, β-adrenergic nervous component; β-FS, β-adrenergic nervous component; β-FS, β-adrenergic nervous component. f-FS, g-adrenergic nervous component. g-FS, g-Adrenergic nervous component.

tion period. TTX (10^{-6} M) abolished the cyclic GMP concentration changes evoked by FS.

The series of experiments summarized in Fig. 1 (thyroids from 200 rats, yielding 50 tests and 50 control preparations) demonstrates directly that electrical stimulation of intrinsic nerves causes marked and complex changes in cyclic nucleotide metabolism. In the steady state (after ~15 min stimulation) there is a substantial and sustained elevation in cyclic AMP concentration. As several different transmitters might be involved it was necessary to carry out experiments using various blocking agents. Table 2 shows the results from experiments in which thyroid preparations were superfused for 20 min in the presence or absence of different kinds of stimuli combined with various blockers. The nerve stimulation-evoked increase in tissue cyclic AMP concentration can be explained as the sum of α - and β -adrenergic components in addition to a substantial non-cholinergic, non-adrenergic contribution. The experiments carried out with specific agonist superfusion (isoprenaline, phenylephrine, ACh and VIP) gave results that fit those obtained with the nerve stimulation (Fig. 2). Although there is no unequivocal indication of a cholinergic nervous component in the cyclic AMP results, the results with cyclic GMP make it clear that nerve stimulation releases ACh which acts on muscarinic rather than nicotinic receptor sites (Table 2). In the steady state, nerve stimulation causes only a modest elevation of cyclic GMP concentration because the elevation expected from the cholinergic component is partly balanced by the ability of α -adrenergic stimulation to decrease cyclic GMP levels (Fig. 2).

The finding that the non-cholinergic, non-adrenergic component of the nerve stimulation-evoked increase in cyclic AMP concentration is matched by the effect of VIP (Fig. 2) implicates VIP as the transmitter involved. If this is so, superfusion with VIP should mimic the entire time course of the nerve stimulation (FS)-evoked changes in cyclic AMP and cyclic GMP concentration obtained in the presence of cholinergic and adrenergic blockers. As seen in Fig. 3, this was indeed the case. Figure 3a shows the time-course changes in cyclic AMP levels following FS and exposure to 10^{-7} M VIP and 75 mM K⁺ in the presence of atropine, propranolol and phentolamine. There is a large and rapid increase in cyclic AMP, maximal after 30-60 s, followed by an abrupt, transient fall after 2-3 min. Thereafter, the level of cyclic AMP rises gradually to a secondary increase, reaching a steady-state level after 16-20 min. Figure 3b shows time-course changes in cyclic GMP concentration during application of FS, 75 mM K⁺ and during exposure to 10⁻⁷ M VIP. The early rapid rise and fall in cyclic AMP is accompanied by a slow, transient increase in cyclic GMP, reaching a maximum after 2-3 min before declining towards the control level.

The series of experiments summarized in Fig. 3 (thyroids from 136 rats, yielding 34 test and 34 control preparations)

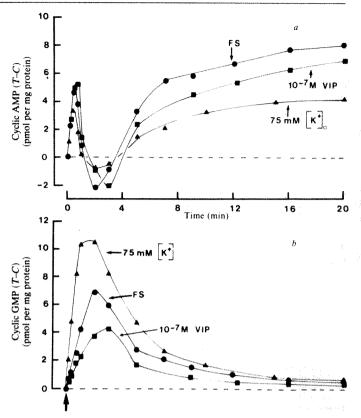

Fig. 3 Time-dependent changes in endogenous cyclic AMP (a) and cyclic GMP (b) levels in rat thyroid segments following FS (\bullet) , during application of 75 mM (\bullet) and (\bullet) and (\bullet) VIP (\bullet) . Atropine $(0.4 \times 10^{-6} \, \text{M})$, phentolamine $(0.4 \times 10^{-6} \, \text{M})$ and propranolol $(0.4 \times 10^{-6} \, \text{M})$ were present in the superfusing solution from the start of the periusion period and throughout the period of stimulation. Cyclic AMP and cyclic GMP concentrations are expressed as in Fig. 1.

demonstrates that the non-cholinergic, non-adrenergic component of the nerve-stimulation response has the opposite initial effect on cyclic AMP levels to that evoked by nerve stimulation in the absence of blockers (Fig. 1). The complex triphasic cyclic AMP response to non-cholinergic, non-adrenergic nerve stimulation is remarkably well reproduced by VIP stimulation. The response is clearly not a non-specific peptide effect because at steady state (20 min), the structurally very different peptide caerulein, used in the same concentration as VIP $(10^{-7} \, \text{M})$, decreases the tissue cyclic AMP concentration (Table 2).

Elevation of extracellular K^+ concentration is generally accepted as a powerful stimulant of neurotransmitter and hormone secretion in a variety of tissues^{13–16}. Figures 1 and 3 demonstrate that high K^+ stimulation does to a large extent mimic the effect of nerve stimulation, although the cyclic GMP

Table 2 Effects of different stimuli (20 min) in the presence or absence of various blocking agents on thyroid cyclic nucleotide levels

			Cyclic AMP			Cyclic GMP	
				(pmol per m	g protein)		
		Test (T)	Control (C)	T-C	Test	Control	T-C

n		37.24	6.28	30.96	3.00	2.61	0.39

The concentrations of blockers used were (M): atropine, 10^{-6} ; propranolol, 5×10^{-6} ; phentolamine, 10^{-5} ; hexamethonium, 10^{-5} . Each value listed under control and test is the result of a single measurement.

changes are more marked than with electrical stimulation and the effects on cyclic AMP metabolism are weaker. High K+ will, in addition to depolarizing intra-thyroidal nerve endings, depolarize the follicular cell membrane^{17,18}, but this is not accompanied by any change in the membrane resistance¹⁸, as the thyroid follicular cell membrane is electrically inexcitable 17. All effects of FS are abolished by TTX19. As thyroid follicular cells do not fire action potentials^{17,18}, the only specific site for TTX action is on intra-thyroidal nerves. Furthermore, ACh, adrenaline, VIP and TSH have no effect on thyroid follicular cell membrane potential and resistance 17,18

The present work has shown that two recognized methods of stimulating nerves in vitro elicit similar changes in thyroid cyclic nucleotide levels, lending powerful support to the hypothesis that intra-thyroidal nerves can influence thyroid follicular cells directly. The pattern of the innervation is complex. Clearly, further work is required before the neurotransmitters responsible can be definitely identified, but the results presented here do show functional cholinergic, adrenergic as

well as non-cholinergic, non-adrenergic innervation of the thyroid gland. As exogenous VIP closely mimics the noncholinergic, non-adrenergic nerve response (Fig. 3) and VIPimmunoreactive nerves have been demonstrated in the thyroid9, it seems likely that the neurotransmitter is VIP or a closely related peptide. Nerve-mediated mechanisms in the control of thyroid function could constitute a sensitive and rapidly responding mechanism, allowing accurate modification of glandular metabolism to accommodate fluctuating requirements of the organism.

The finding that all the stimulation procedures resulted in changes in both cyclic AMP and cyclic GMP levels emphasizes the danger of focusing exclusively on cyclic AMP metabolism. The cyclic nucleotide changes generally display a reciprocal pattern which has also been observed in the frog heart 20 and the pancreas¹³. The functional implication of this complex interrelationship obviously deserves much further attention.

A differentiation factor required for the expression of cytotoxic T-cell function

David H. Raulet* & Michael J. Bevan*

Center for Cancer Research and Department of Biology, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139, USA

Effector cytotoxic T lymphocytes (CTLs) are induced from resting precursors (small lymphocytes) which do not express cytotoxic activity. The process of CTL activation, which occurs in 2-7 days following mitogen or antigen stimulation, thus involves a differentiation event and normally also involves proliferation. These events in CTL activation seem to be induced, at least in part, by soluble, antigen-nonspecific mediators which reach the CTL precursor as a consequence of cell-cell interactions during the immune response. The initial evidence for this was the finding that in addition to CTL precursors, Ia-positive macrophage-like accessory cells1-4, and helper T cells⁵⁻¹⁰ are required for the induction of CTL activity in vitro. Furthermore, the requirement for accessory cells can be replaced with factors present in concanavalin A (Con A)induced cultures of spleen cells11. There is evidence that T-cell products such as interleukin-2 (IL-2, formerly T-cell growth factor)¹¹⁻¹⁵ as well as accessory cell products, such as interleukin-1 (IL-1, formerly lymphocyte activating factor) 4,15 involved in T-cell activation, although the precise roles of these factors in CTL activation are poorly understood. Here we provide evidence for a factor, different from IL-1 and IL-2, which is present in supernatants of Con A-activated mouse spleen cells and is required for the differentiation of CTL precursors into active CTLs.

The experimental system used involved the Con A-mediated polyclonal induction of CTLs from T-cell populations¹⁶. The responding T-cell population was depleted of accessory cells so that Con A-induced proliferation 17 and differentiation were

dependent on exogenous factors. CTLs were assayed after 40 h for cytotoxic activity against 51Cr-labelled P815 targets in the presence of phytohaemagglutinin (PHA); this assay registers the activity of all CTLs, regardless of their antigen specificity^{16,18}. We wished to determine whether IL-2, which is assayed by its capacity to maintain the proliferation of cloned CTLs¹⁹, is sufficient to support the Con A-induced differentiation of CTLs from accessory cell-depleted T-cell populations. In initial experiments we compared two sources of IL-2: supernatants from Con A-activated spleen cell cultures (spleen Con-A Sn)^{12,13} and supernatants from cultures of Con A-activated T-cell hybridoma AOFS 21.10.9 cells (AOFS Con A Sn). AOFS 21.10.9 (provided by Drs J. Kappler and P. Marrack) is a cloned, murine T-cell hybridoma^{20,21} which releases IL-2 on stimulation with Con A or antigen.

Our initial observation was that T cells activated with Con A plus AOFS Con A Sn were induced to proliferate (Fig. 1b), but did not mature into active CTLs after 40 h (Fig. 1a). In contrast, T cells activated with Con A plus spleen Con A Sn were efficiently induced to differentiate into cytotoxic cells

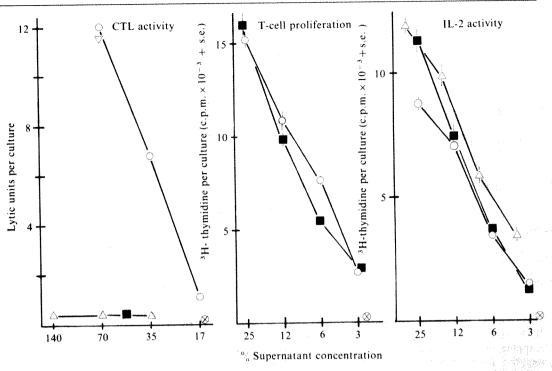

Table 1 Lyt-2-positive T cells proliferate in response to Con A plus AOFS Con A Sn

	³ H-thymidine (c.p per culture inc	
Additions to test culture	T cells	Lyt-2-positive T cells
	0.3 ± 0.1	0.2 ± 0.1
Con A (2 µg ml ⁻¹)	3.4 ± 0.6	1.6 ± 0.2
Con A + 25% spleen Con A Sn	152.4 ± 4.1	357.9 ± 10.4
Con A+12% spleen Con A Sn	108.2 ± 3.2	246 5 ± 11.6
Con A + 25% AOFS Con A Sn	159.1 ± 9.2	336.8 ± 25.6
Con A + 12% AOFS Con A Sn	99.4±32	307 8±27 5

T cells were purified as described in Fig. 1 legend. Lvt-2-positive T cells were purified from accessory cell-depleted T-cell populations by positive selection on plastic dishes³⁰ coated with monoclonal anti-Lyt-2 antibodies (N. Landau and M J B., in preparation). 60×10^6 T cells in 4 ml were incubated for 40 min in the cold on a 100-mm Petri dish which had been coated for 1 h in the cold with 20 µg of purified AD4(15)³¹ anti-Lyt-2 antibodies. The non-adherent cells were removed, the plates were washed six times and the adherent cells (17% of applied cells in this experiment) were removed from the dish by pipetting. T-cell populations selected in this fashion are >95% Lyt-2+. The proliferative response of T cells and Lyt-2+ T cells were determined as in Fig. 1 legend.

^{*} Present addresses Department of Pathology, University of Pennsylvania, Philadelphia, Pennsylvania 19104, USA (D H R), Department of Immunology, Scripps Clinic and Research Foundation, La Jolla, California 92037, USA (M J B)

Fig. 1 IL-2 is not sufficient to support the differentiation of CTLs from accessory celldepleted T-cell populations. Spleen Con A Sn^{12,13} was prepared by culturing spleen cells $(7 \times 10^6 \text{ cells ml}^{-1})$ from BALB.K mice with 2 ug ml Con A for 24 h in RPMI-1640 medium containing 5% heat-inactivated fetal calf serum, 50 µM 2-mercaptoethanol, 0.02% 5 mM HEPES, glutamine, 50 µg ml⁻¹ gentamycin, 100 Uml penicillin and 100 µg ml-1 streptomycin (complete medium). AOFS Con A Sn^{20,21} was prepared hv activating AOFS-21.10.9 cells (5) 105 cells ml-1) with µg ml-1 Con A for 24 h in complete medium. The cells were removed by centrifugation and the supernatants sterilized by filtration. Excess Con A was removed from AOFS Con A Sn by passage through a column of Sepharose-4B which had been coupled with p-aminophenyl-a-D-mannopyranoside. centrated AOFS Con A Sn was prepared from AOFS Con A Sn (prepared as above,

except with 0.5% fetal calf serum and 5 μg ml⁻¹ Con A) by precipitation with ammonium sulphate. The fraction that precipitated between 40 and 80% ammonium sulphate, which contains virtually all the IL-2 activity, was resuspended in 1/30 the original volume, and dialysed extensively against RPMI-1640 medium; the concentrations of concentrated AOFS depicted as based on the original volume. Accessory cell-depleted T-cell populations were prepared by passing 5×108 lymph node cells from BALB.K mice through a column containing 3.5 g of washed nylon wool³², and treating the non-adherent cells with ATH anti-ATL serum (anti-Ia* serum) and rabbit complement essentially as described previously³¹. Surviving cells ('T cells') were washed twice before use. The capacity of the supernatants to induce the differentiation of CTLs from accessory cell-depleted T-cell populations was determined by incubating aliquots of 4×10^6 T cells in wells of Costar 3524 plates with $2 \mu g$ ml⁻¹ Con A and the indicated concentration of supernatant in a total volume of 1.5 ml complete medium. After 40 h at 37 °C in an atmosphere of 5% CO₂ in air, the lectin was dissociated from the activated cells by incubating them with α -methyl mannoside (50 mM) for 10 min at room temperature. The cells were washed once, resuspended in 1 ml and serial dilutions of this assayed for cytotoxicity against ⁵¹Cr-labelled P815 targets in the presence of 10 μ g ml⁻¹ PHA-P¹⁶ (Difco) for 6 h essentially as described previously³¹. Lytic units are a relative measure of CTL activity, and are calculated from complete titrations of effector cells versus the per cent specific lysis of target cells. One lytic unit³³ is the number of CTLs which will cause 30% specific lysis of 4×10^4 target cells in this assay period. Comparable numbers of cells were recovered from Con A-activated cultures supplemented with either spleen Con A Sn or AOFS Con A Sn. Con A-dependent proliferation of accessory cell-depleted T-cell populations was determined by inc

Fig. 1a, b). (Cytotoxic cells induced with Con A and spleen Con A Sn were sensitive to complement-mediated lysis with monoclonal anti-Thy-1 or anti-Lhy-2 antibodies, and are thus conventional CTLs (data not shown).) As can be determined from the titration curves shown in Fig. 1c, the two kinds of supermatant had comparable levels of IL-2, and of factors which induce the proliferation of Can A-activated accessory cell-depleted T cells (Fig. 1b). In addition, AOFS Con A Sn did not suppress the induction of CTLs by spleen Con A Sn when included in the same culture (Fig. 1a). These results suggest that a factor(s) other than IL-2, present in spleen Con A Sn but not in AOFS Con A Sn, is required for CTL differentiation. We call this factor 'CTL differentiation factor' (CDF).

Because AOFS Con A Sn induces T-cell proliferation without inducing differentiation into CTLs, it seemed possible that CTL proliferation and differentiation were controlled by separate factors, IL-2 and CDF, respectively. However, although AOFS Con A Sn supports the growth of CTL lines, it was possible that CTL precursors do not proliferate in response to Con A plus AOFS Con A Sn.

To ascertain whether AOFS Con A Sn plus Con A induces the proliferation of Lyt-2-positive T cells (that is, the T-cell subset which contains CTL precursors²²), we purified Lyt-2-positive T cells by absorption to plastic dishes coated with monoclonal anti-Lyt-2 antibodies, and compared the proliferative responses of these cells with the responses of unselected T cells. The proliferative response of Lyt-2-positive T cells to Con A plus AOFS Con A Sn was actually larger than the com-

parable response of unselected T cells (Table 1). In a related experiment, we determined whether Con A plus AOFS Con-A Sn induced the blast transformation of Lyt-2-positive T cells in cultures of unseparated T cells. Density step gradients were used to isolate blast cells (activated cells) from 40-h cultures of accessory cell-depleted T-cell populations activated with Con A plus AOFS Con A Sn. The proportion of these T cells susceptible to lysis with monoclonal anti-Lyt-2.2 antibodies plus complement (27%) did not differ significantly from the proportion of Lyt-2-positive blast cells in cultures activated with Con A plus spleen Con A Sn (32%). Thus, we find no evidence that AOFS Con A Sn is less effective in inducing the proliferation or blast transformation of CTL precursors than is spleen Con A Sn.

In further experiments we determined some of the physicochemical properties of CDF. Spleen Con A Sn was treated in various ways, and then tested for CDF and IL-2 activities. Dialysis against culture medium resulted in a minimal loss of CDF activity, which shows that CDF is a macromolecule (Table 2). Furthermore, treatment of CDF-containing supernatants with trypsin abolished CDF activity, even when the digested sample was supplemented with AOFS Con A Sn for the CDF assay. Thus, CDF has a polypeptide component which is essential for activity. Dialysis of spleen Con A Sn against an acidic (pH 2.0) buffer abolished CDF activity but had no effect on IL-2 activity. Thus, unlike IL-2²³, CDF is acid sensitive.

The finding that CDF activity is abolished by digestion with trypsin is one piece of evidence that CDF is not identical to

For expts 1 and 2, 10-ml samples of spleen Con A Sn were either dialysed against two changes (250 ml each) of complete medium (see Fig. 1 legend) or dialysed against 0.1 M glycine, 0.15 M NaCl, pH 2.0, for 18 h, followed by dialysis against two changes (250 ml each) of complete medium. For expt 3, we used serum-free spleen Con A Sn prepared as described in Fig. 1 legend, except that the medium was supplemented with 10 µg ml⁻¹ of bovine serum albumin instead of serum. Samples of serum-free spleen Con A Sn were treated with 20 µg ml⁻¹ trypsin (TPCK treated, Millipore) for 1.5 h at 37 °C, at which time fetal calf serum (which contains trypsin inhibitors) was added to a final concentration of 5%. As a control (expt 3, 4th line) a sample of serum-free spleen Con A Sn was incubated in identical conditions, except that trypsin was added only after the addition of serum. In a separate experiment, treatment of supernatants with Difco trypsin also abolished CDF and IL-2 activities (not shown). Treated supernatants were sterilized by filtration and tested for CDF and IL-2 activities as described in Fig. 1 legend, except that cytotoxic activity is depicted in terms of the % specific lysis of target cells at a single effector to target ratio (25:1). In one case (expt 3, 3rd line), the test supernatant was supplemented with concentrated AOFS Con A Sn (to an adjusted concentration of 140%) for the CDF assay.

IL-1, which is trypsin insensitive²⁴. In addition, we have tested IL-1 preparations from two sources (Dr S. Mizel, and Drs J. Kappler and P. Marrack) in our assay: both preparations were negative for CDF activity, even if supplemented with excess AOFS Con A Sn before the test (data not shown). Taken together, our results suggest that CDF activity resides in a molecular species that is distinct from IL-1 and IL-2.

To demonstrate further the molecular independence of IL-2 and CDF, we attempted to remove IL-2 selectively from spleen Con A Sn in such a way that the supernatant retained CDF activity. IL-2 was depleted from spleen Con A Sn by absorption with cells of an IL-2-dependent cloned CTL line, CTLL-15H (ref. 25). Following absorption, the supernatants were dialysed and tested for CDF and IL-2 activities. Although virtually all IL-2 was removed (Fig. 2b), the absorbed supernatants induced the differentiation of CTLs with ~50% the efficiency of unabsorbed spleen Con A Sn (Fig. 2a). A mixture of the absorbed spleen Con A Sn and AOFS Con A Sn was as effective as unabsorbed spleen Con A Sn in inducing CTL activity (Fig. 2a). From these data, we conclude that CDF is separable from IL-2;

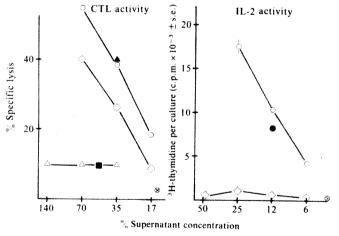

Fig. 2 Spleen Con A Sn, depleted of IL-2, induces CTL differentiation. IL-2 was depleted from spleen Con ASn by absorption with $2\times10^6\,\mathrm{ml}^{-1}\,\mathrm{CTLL}\text{-}15\mathrm{H}^{25}$ (IL-2-dependent CTL line) cells for 24 h at 37 °C. Cells were removed by centrifugation and the supernatant was dialysed against two changes of 250 ml complete medium and sterilized by filtration. T cells were prepared and assays were performed as for Fig. 1, except that instead of lytic units CTL activity is expressed as the % specific lysis at an effector to target ratio of 25:1. Supernatants tested were spleen Con A Sn (○), IL-2-depleted spleen Con A Sn (♦), AOFS Con A Sn (■), AOFS Con A Sn concentrated by ammonium sulphate precipitation (% Sn based on original volume) (A), a mixture of 35% IL-2-depleted Con A Sn and 30% concentrated AOFS Sn (▲), a mixture of 12% spleen Con A Sn and 25% IL-2 depleted spleen Con A Sn (●), and no supernatant (⊗).

furthermore, because the absorbed supernatant had no measurable IL-2 activity and did not inhibit the IL-2 assay significantly (Fig. 2b), it is unlikely that CDF is simply a modified form of IL-2 with both IL-2 and CDF activities.

It is interesting that we find no requirement for exogenous IL-2 in this assay system (Fig. 2a), particularly as IL-2 is implicated in most models of CTL differentiation $^{6.7,11-14}$. In fact, our data do not rule out the involvement of IL-2 in CTL differentiation, because it is possible that Con A-activated T cells in the test culture produce IL-2 in response to factors in the IL-2-depleted spleen Con A Sn.

The absence of a requirement for factors other than IL-2 in CTL induction in other published reports may be because in such studies, spleen Con A Sn was the sole source of IL-2, and biochemical separation of IL-2 from other factors in spleen Con A Sn is often difficult. In addition, we have found that with extended culture periods (4-5 days) CTL activity appears in cultures to which no exogenous CDF was added (data not shown). This may be due to in situ production of CDF by cells in the test culture.

We do not know whether CDF is required to maintain the CTL activity of mature CTLs. The factor does not seem to bind avidly to cloned, mature CTLs, because in conditions in which IL-2 is depleted from spleen Con A Sn by absorption to IL-2-dependent, cloned CTLs, CDF activity is not depleted (Fig. 2).

Recent studies of soluble factors involved in the antibody response have provided evidence for separate factors which regulate the growth and differentiation to immunoglobulin secretion of anti-immunoglobulin or antigen-activated B cells²⁶⁻²⁹. Our data suggest that CTL activation may also involve growth-inducing and separate differentiation-inducing activities-IL-2 and CDF, respectively. Further work will be required to determine the cellular source and specific mechanism of action of CDF.

This work was supported by USPHS grant AI-14269. We thank Lorraine Gemmell for technical assistance, Fern Brown for typing the manuscript, and Dr David Parker for performing the absorption of Sp Con A Sn with CTLL cells.

Interferon inhibits the suppressor T cell response of delayed-type hypersensitivity

J. Knop*, R. Stremmer*, C. Neumann*, E. De Maeyer† & E. Macher*

* Hautklinik der Universität Münster, von-Esmarch-Strasse 56, D-4400 Munster, FRG † Institut Curie, Section de Biologie, Centre Universitaire, F-91405 Orsay, France

We have recently shown that pretreatment of BALB/c mice with Corynebacterium parvum preferentially inhibits suppressor T lymphocytes (T_s) which have been induced by an epicutaneous antigen overload or by intravenous (i.v.) injection of 2,4dinitrobenzenesulphonic acid (DNBSO₃)². Serum obtained 24 h after C. parvum injection had a similar suppressive effect on T₈ but no effect on T effector lymphocytes of delayed-type hypersensitivity $(T_{DH})^3$. Inhibition of T_8 by this serum could be neutralized by an anti-interferon globulin4. A crude mouse fibroblast interferon (IFN) preparation also inhibited the T_s response4, which suggested that IFN in C. parvum serum might be the Ts inhibitory factor. We have now studied the effect of an electrophoretically purified mouse interferon (IFN-a and β) preparation on the T_s response to dinitrofluorobenzene (DNFB) in BALB/c mice. Small amounts (1,000 U) of the preparation inhibited the generation of T₅ by DNBSO₃ in vivo, and the function of T_s both in the recipient animals when injected i.v. 2 h after transfer of the Ts and after incubation of the spleen cells from tolerant animals with interferon before transfer into recipients. The TDH response was not affected by this amount of interferon.

BALB/c mice were sensitized to DNFB by the method of Phanuphak et al. $^{1.5}$. Briefly, 15 μ l of 0.5% DNFB were painted on to the shaved abdominal skin of BALB/c mice on two consecutive days; 5 days later one ear was challenged with 0.3% DNFB. Ear swelling was measured 24 h later using an engineer's micrometer and expressed as 10⁻² mm difference in thickness between the unchallenged and challenged ears. Increasing the sensitizing dose of DNFB (50 μ l 0.5%) resulted in diminished contact sensitization¹. Sy et al.⁶ have shown that the diminished immune response is due to the generation of T_s by the antigen overload.

Interferon was prepared in mouse C-243 cells by induction with Newcastle disease virus. It was purified by sequential chromatography on Sepharose-bound poly(U) and anti-interferon globulin as previously described. Electrophoretic analysis on polyacrylamide gel, followed by staining with Coomassie brilliant blue, revealed only the three interferon bands, corresponding to molecular weights of 35,000, 28,000 and 22,000, and no contaminating bands. The 35,000- and 28,000molecular weight species correspond to mouse IFN- β and the 22,000 species to mouse IFN- α (ref. 8). The purified interferon was stabilized with 0.5% BALB/c serum.

Intravenous injection of 1,000 U (Fig. 1c) or 100 U (Fig. 1d) interferon 2 h after the first sensitization with an antigen overload (50 µl DNFB) increased ear swelling compared with untreated or buffer-treated controls. Ear swelling was not diminished in animals treated with interferon 2 h after optimal sensitization (Fig. 1f-j), which shows that TDH cells were not affected by the amount of interferon used. The enhancement of T_s-mediated suppression of contact sensitivity by interferon after antigen overload suggests that interferon inhibits the manifestation of the T_s response as discussed previously¹

In the following experiments (Figs 2-4) T₈ were induced by i.v. injection of 15 mg DNBSO₃ per mouse^{2,5,9}. To confirm the presence of T_s, spleen cells (1×10° cells per mouse) prepared 6 days after DNBSO₃ injection from donor spleens were transferred to naive recipients. They were sensitized on two consecutive days with an optimal amount of DNFB and challenged 5 days later. Intravenous injection of 1,000 U interferon 2 h after i.v. injection of DNBSO₃ inhibited the generation of T₅ (Fig. 2d); thus no suppression could be transferred with the spleen cells of interferon-treated animals to the recipients as compared with the untreated (Fig. 2b) or buffer-treated (Fig. 2c) controls. One hundred units of interferon (Fig. 2e) were marginally effective, ten units (Fig. 2f) had no effect. In the following experiment the effect of interferon on Ts in the recipient animals was investigated by i.v. injection of the recipients with interferon 2 h after T_s transfer (Fig. 3). The activity of the transferred Ts was completely abolished by treating the recipient animals with 1,000 U interferon (Fig. 3d). Inhibition of T_s activity has also been observed in recipient animals injected with C. parvum or serum obtained from C. parvum-treated animals^{2,3}

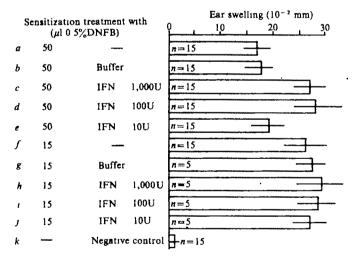

Fig. 1 Effect of interferon on contact sensitivity in animals sensitized with an optimal amount of DNFB (15 µl) and by epicutaneous antigen overload (50 µl). BALB/c mice, 10-12 weeks old, were sensitized with 15 µl (optimal) or 50 µl 0.5% DNFB by painting the shaved abdominal skin on two consecutive days. Interferon or buffer (0.5 ml per mouse) was injected i.v. once 2 h after the first sensitization. On day 5, ear challenge was performed by painting the right ear with 20 µl 0.3% DNFB; 24 h later ear thickness was measured and ear swelling was calculated as the difference in ear thickness between the unchallenged (left) and challenged (right) ear. The results of three experiments are presented in this figure and in Figs 2-4 as mean ear swelling ± s.d All data were analysed by one-way analysis of variance followed by Scheffe's test for least significant difference. Statistical analysis. group a not different from b; group c increased over a and b, group d increased over a and b; group e not different from a and b; group f not different from g, h, k, j; group k (nonsensitized animals, ear challenged) less than all other groups.

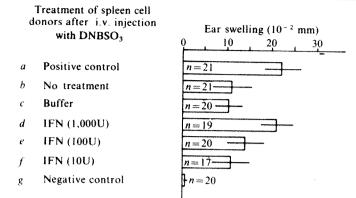

Fig. 2 Effect of interferon on the T_S response in the spleen cell donor treated with DNBSO₃ i.v. Mice treated with DNBSO₃ i.v. (15 mg per mouse) to induce T_S were injected i.v. with interferon or buffer 2 h later. After 6 days spleen cell suspensions were prepared and transferred by i.v. injection to naive recipients (1×10⁸ cells per mouse). The recipients were sensitized with 15 μl 0.5% DNFB and challenged as described in Fig. 1 legend. The results are expressed as mean±s.d. from 2-3 experiments. a, Optimally sensitized animals. Groups b-f, ear swelling in recipients receiving spleen cells from DNBSO₃-treated donors: b, no further treatment of donors; c, donors injected i.v. with 0.5 ml buffer; d-f, donors injected i.v. with 0.5 ml interferon (1,000, 100, 10 U). g, Unsensitized, ear-challenged control. Statistical analysis: group b less than a; c less than a; c not different from b; d not different from a; d increased over b and c; e, f not different from b, c.

Figure 4 shows the results of experiments in which spleen cells from tolerized animals were treated in vitro with interferon before transfer to the recipient animals. The spleen cells were prepared from animals treated with DNBSO₃ 6 days earlier and 1×10° per ml were incubated with 10,000 U interferon per ml for 2 h at 37 °C, or were incubated similarly in the control buffer or transferred immediately after preparation to the recipient animals. After incubation the cells were washed three times in Dulbecco's minimal essential medium and 1×10^8 cells per mouse injected i.v. into the recipient animals. The incubation and washing procedure of the buffer-treated spleen cells did not affect the suppressive capacity of these cells in the recipient animals (Fig. 4c) compared with the non-incubated spleen cells (Fig. 4b). Incubation of the spleen cells with interferon, however, completely abolished their capacity to transfer suppression (Fig. 4d).

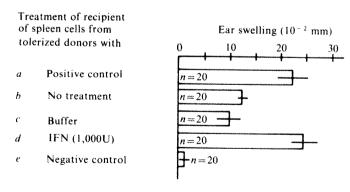

Fig. 3 Effect of interferon treatment of the recipients of T_S on the T_S response. Groups of mice were tolerized as described in Fig. 2 legend. Spleen cell suspensions were prepared after 6 days and transferred to recipients $(1\times10^8~{\rm cells}~{\rm per}~{\rm mouse})$ which were treated with buffer or interferon by i.v. injection 2 h after cell transfer. Sensitization and challenge of the recipients was performed as described in Fig. 1 legend. a, Optimally sensitized animals; b-d, ear swelling in recipients treated 2 h after T_S cell transfer with: b, no treatment; c, buffer; d, interferon. Statistical analysis from two to three experiments: group b less than a; c less than a; c not different from b; d increased over b and c; d not different from a.

The results reported here show that T_s of delayed-type hypersensitivity are inhibited by electrophoretically pure interferon; the in vitro treatment of Ts with interferon revealed a subpopulation of immune regulatory lymphocytes highly sensitive to interferon (1 U of interferon inhibits T_s cells present in 10^s spleen lymphocytes). The T_{DH} response is not affected by the amount of interferon which inhibits T_s. Inhibition of T_{DH} probably requires much higher amounts as suggested by the inhibitory effects of interferon on expression of delayed-type hypersensitivity to sheep red blood cells and picryl chloride 10. Interferons have been shown to affect the immune reaction in vitro and in vivo (for review see ref. 11). Interferon augments the cytotoxic activity of natural killer cells¹² and inhibits cell-mediated immune responses in vivo¹⁰ and in vitro¹³. Its effects on cell-mediated immunity, as measured in experimental contact allergy induced by picryl chloride or in delayed reaction to sheep red blood cells¹⁰, strictly depends on the interferon dose used and the timing of injection. Whereas application of interferon before sensitization results in a decreased immune

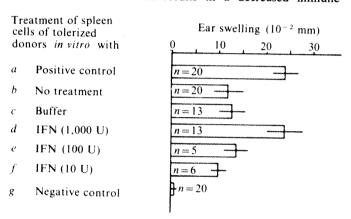

Fig. 4 Treatment of spleen cells from tolerized donors with interferon in vitro before transfer. Spleen cell suspensions were prepared from tolerized donors as described in Fig. 2 legend; 1×10^9 cells were incubated at 37 °C for 2 h, 7% CO₂ in 1.0 ml Dulbecco's minimal essential medium containing control buffer or interferon. After incubation the cells were washed three times with the medium and injected i.v. into recipients $(1 \times 10^8 \text{ cells per mouse})$. Recipients were sensitized and challenged as described in Fig. 1 legend. a, Optimally sensitized animals; b-f, ear swelling in animals receiving spleen cells treated in vitro with: b, no treatment; c, buffer; d-f, interferon $(1,000, 100, 10 \text{ U per } 1 \times 10^8 \text{ spleen cells})$. Statistical analysis of one to two experiments: groups b, c less than a; c not different from b; d increased over c, b; d not different from a; e, f not different from b, c.

response, injection after sensitization increases the immune response 14. In our system which is able to differentiate between T_{DH} and T_S, small amounts of interferon were capable of increasing the immune responsiveness by selectively suppressing T_s. This probably provides an important clue to the observed enhancing effect of IFN. At the moment it is not clear which T_s (suppressing the afferent or efferent limb of the immune response) may be preferentially inhibited by interferon. The mechanism of interferon-mediated inhibition of T_s may be explained by the suppressive effect on lymphocyte proliferation which has been observed in several in vitro systems 15. Inhibition of T_s proliferation would explain the inhibitory effect of interferon in the donor, the recipient and the in vitro treatment of Ts if one assumes that further clonal expansion is required for the T_s function in the recipient animals. An alternative explanation would be inhibition of effector function of T_s by interferon or an indirect action on T_s by contra suppressor cells¹⁶

The results obtained with the purified interferon preparation confirm our previous findings that T_s inhibition by $C.\ parvum^2$ and serum obtained from $C.\ parvum$ -treated animals³ is mediated by interferon⁴. Although it is widely accepted that interferon is immunosuppressive in vitro and in vivo, recent

observations17 showing that interferon enhanced the specific antibody response to sheep red blood cells in vivo and our present results suggest a stimulatory effect of interferon. The interference of interferon with Ts may augment immune responses and be an important protective mechanism against viral and bacterial infections.

We thank Maria-Theres Keuck and Reinhild Luster-Haggeney for technical assistance and Brunhilde Scheibel for typing the manuscript. This work was supported by the Deutsche Forschungsgemeinschaft (grant KN 120/4).

Primary structural studies of the Oa-2 alloantigen: implications for the evolution of the MHC

Mark J. Soloski, Jonathan W. Uhr & Ellen S. Vitetta

Department of Microbiology, University of Texas Health Science Center, Dallas, Texas 75235, USA

The murine major histocompatibility complex (MHC) contains a number of loci encoding cell-surface glycoproteins of molecular weight (MW) 40,000-45,000 which are noncovalently associated with β_2 -microglobulin. The products of this large multigene family, collectively referred to as class I gene products, include H-2K,-D,-L and -R, which are encoded by the H-2 complex, and Qa-1, -2 and TL, encoded by the Tla region telomeric to H-2 (refs 1-5). Functional studies have shown that the H-2K, -D and -L gene products serve as important self-recognition structures in immune responses^{6,7}; a functional role for the other class I gene products has not been established. Tryptic peptide map comparisons and primary sequence analyses have indicated that H-2K, -D and -L are 70-85% homologous with respect to their amino acid sequences⁸⁻¹⁰. The data, however, have failed to reveal structural features unique to gene products of a given locus. Recent tryptic peptide map comparisons of the Tla gene products, Qa-2 and TL, have shown that Qa-2, H-2K and -D are more closely related to each other than to TL^{11,12}. Here we present the NH2-terminal sequence of the Qa-2 alloantigen. Our results, together with those of previous studies, show that Qa-2 has significant homology to H-2 antigens but differs in that Qa-2 molecules lack extensive polymorphism and the Qa-2 heavy chain has two additional NH2-terminal amino acids and several critical amino acid interchanges compared with H-2 antigens.

conventional antiserum to Qa-2 alloantigens $(B6.K1\alpha B6)$ is potentially polyvalent with possible reactivities to Qa-2, -3, -4 and -5 (ref. 13). However, the immunoprecipitating activity of the K1aB6 serum is directed against the Qa-2 alloantigen as absorption of this serum with thymus (Qa--2+3-4-5-) or EL-4 lymphoma (Qa-2+3-4+5-) cells removes

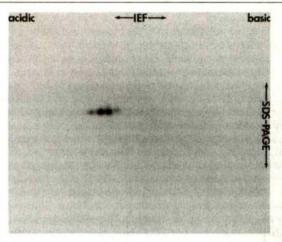

Fig. 1 Two-dimensional gel electrophoresis of the Qa-2 alloantigen. Spleen cells (5×10^7) from C57BL6/J (B6) mice were radiolabelled by lactoperoxidase-catalysed iodination31 labelled cells were washed with phosphate-buffered saline (PBS) and lysed in PBS containing 0.5% NP40 at 4 °C for 15 min. Nuclei and debris were removed by centrifugation and the cytoplasmic extract dialysed at 4 °C against PBS for 16 h. The dialysed extract was centrifuged at 10,000 g for 15 min to remove insoluble material before immunoprecipitation. Immunoglobulin was precleared from the lysate by incubation with rabbit anti-mouse immunoglobulin (RαMIg, 200 μl per 5×107 cells) at 4°C for 45 min, then protein A-bearing Cowan I strain of Staphylococcus aureus was added and the mixture incubated at 4 °C for 45 min. Immunoglobulin-depleted lysates were then treated with normal mouse serum (200 µl per 5×10⁷ cells, 4 °C, 45 min), followed by two additions of Cowan I strain of S. aureus. The precleared lysate was then reacted with anti-Qa-2 serum at 4°C for 45-60 min. Immune complexes were removed by adding goat anti-mouse immunoglobulin (Ga MIg). The immunoprecipitates were washed three times with PBS containing 0.1% SDS, 0.25% NP40 and 0.2% deoxycholate followed by one wash with PBS. The washed immunoprecipitate was then analysed by two-dimensional gel electrophoresis as described by O'Farrell³² and modified by . Gels were exposed to Fuji Rx X-ray film using a Dupont Cronex Lightning-plus intensifying screen. Exposure was for 1-2 weeks at -70 °C. IEF, immunoelectrophoresis; SDS-PAGE, SDSpolyacrylamide gel electrophoresis.

all immunoprecipitating activity14. Since it was critical for sequence studies to establish that this antiserum precipitates a single species of 40,000-MW heavy chain, Qa-2 antigens were immunoprecipitated from lysates of radioiodinated C57BL/6 spleen cells and the immunoprecipitates were analysed by twodimensional gel electrophoresis. As shown in Fig. 1, the anti-Qa-2 antiserum precipitates several acidic 40,000-MW species. The observed microheterogeneity in Qa-2 is typical of cellsurface glycoproteins varying only in the sialic acid content of their carbohydrate moieties. Consistent with this interpretation is the observation that pretreatment with neuraminidase results in a shift to more basic species (data not shown). These results suggest that a single polypeptide chain carries the serologically defined Qa-2 determinant.

H-2 gene products have extensive polymorphism, for example, 56 alleles at the H-2K locus and 45 at the H-2D locus 15. As our peptide mapping studies indicated that the Qa-2 molecules show extensive homology with H-2 gene products, it was important to determine whether Qa-2 exhibited strainrelated polymorphism. So far, two Qa-2 alleles have been defined by the ability of standard antisera (B6.K1\alpha B6) and complement or cytotoxic effector cells either to kill (Qa-2a) or not kill $(Qa-2^b)$ spleen cells from various inbred mouse strains 13,16 . Both the serological and cellular approaches have failed to detect polymorphism associated with the Qa-2^a allele. It is not clear whether the Qa-2b allele is a true 'null' allele or whether the results are due to a reagent limitation. A failure to detect polymorphism by immunological techniques does not indicate the absence of primary structural polymorphism. Thus

the gene products of the Ss/Slp or H-2L loci show no serologically detectable polymorphism, yet biochemical analysis of the isolated molecules detects structural variations^{17,18}.

We immunoprecipitated Qa-2 alloantigens from various inbred strains bearing the Qa-2a allele and compared their primary structures by tryptic peptide mapping. The sensitivity of this technique in detecting a single amino acid change in a given molecule has been well documented¹⁹. Figure 2 shows that the arginine-labelled tryptic peptide maps of Qa-2 molecules isolated from three different inbred strains (A/J, BALB/c and the wild congeneic B10.KPB-128) are identical. We have examined several additional Qa-2a inbred strains including B10, B6, DBA/1, SWR, DBA/2 and the wild congeneic B10.KEA5; the Qa-2 molecules isolated from these strains also have identical tryptic peptide maps. Note that the background strain used to construct the wild congeneic strains (B10.BR) carries the Qa-2^b allele^{20,21}. Thus, in those wild congeneic strains typed Qa-2^a, the Qa-2 locus probably derived from the wild mouse population. When the allelic products of the H-2K and -D loci were examined using similar methods, only 20-50% of their tryptic peptides were identical⁸ observations indicate that the gene products of the Qa-2 locus do not exhibit the extensive allelic structural variation typical of the most well characterized members (that is, H-2K, -D and -L) of this multigene family. Limited polymorphism may be a property of Tla gene products as serological studies have distinguished two alleles for the Qa-1, -3, -4 and -5 loci and five alleles for the Tla locus¹³. Thus, the present and previous peptide mapping studies present a paradox; Qa-2 is strikingly homologous with H-2 antigens, but is the first member of the class I (or class II) MHC antigens that is not highly polymorphic.

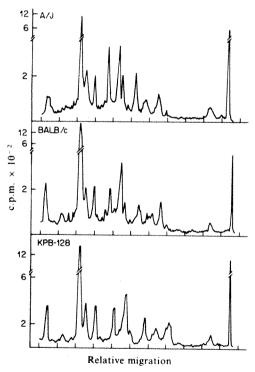

Fig. 2 Tryptic peptide maps of Qa-2 isolated from several inbred mouse strains. Qa-2 molecules metabolically labelled with 3 H-arginine were isolated by immunoprecipitation and SDS-PAGE from a lysate of concanavalin A (Con A)-stimulated spleen cells 11 . The isolated molecules were digested with trypsin and the resulting peptides analysed by cation-exchange chromatography on Technicon chromobeads type P^{11} . Before chromatography, the sample was mixed with 14 C-arginine-labelled P3 myeloma κ chains, which had been digested with trypsin. These peptides served as internal markers facilitating the comparison of each peptide map. The figure shows the arginine-labelled tryptic peptide maps of Qa-2 isolated from A/J (top), BALB/c (middle) and B10.KPB-128 (bottom).

Fig. 3 Partial NH₂-terminal sequence of Qa-2 compared with other class I molecules. Qa-2 molecules metabolically labelled with a single amino acid were immunoprecipitated from extracts prepared from Con A-stimulated B6 spleen cells. The immunoprecipitates were denatured, reduced and the 40,000-MW Qa-2 molecule isolated by SDS-PAGE¹¹. The isolated Qa-2 molecules were lyophilized, re-dissolved in H₂O with 1 mg human γ-globulin as carrier, and dialysed against H₂O to remove free SDS. The dialysed Qa-2 molecule was loaded on to a Beckman 890C sequencer for analysis^{22,23}. In each sequencing run, a ³⁵Smethionine-labelled light chain was used as an internal standard. The methionine residues at positions 4, 11 and 13 allowed the determination of a repetitive yield. Thiazolinone derivatives were evaporated under nitrogen and counted in a liquid scintillation counter. Assignments were based on: (1) the appearance of a peak of radioactivity in a given sequencing step; (2) the ability of multiple peaks to fit a standard repetitive yield curve as determined for each run using the ³⁵S-methionine immunoglobulin light-chain standard. The H-2 sequences were obtained from Coligan et al. 1 The upper panel shows the non-aligned H-2Kb and Qa-2 assignments. The lower panel shows the Qa-2 assignments aligned with several H-2 sequences after the introduction of a 2-amino acid gap in the Qa-2 sequence after position 3. Asterisks in the lower panel denote the positions of valine and arginine residues in H-2 molecules, and their counterparts in other species, which are absent from the Qa-2 molecule. The solid lines indicate residues which are identical to those in H-2K

To elucidate the primary structure of the Qa-2 alloantigen, we analysed the NH₂-terminal sequence. Qa-2 alloantigen labelled with a single ³H-amino acid was isolated from lysates of mitogen-activated B6 splenocytes which have been shown to be particularly enriched for the expression and synthesis of Qa-2 (ref. 11). The 40,000-MW heavy chain of Qa-2 was prepared by electrophoresis of the immunoprecipitate and used for NH₂-terminal sequencing^{22,23}. Figure 3 (top) shows the partial NH₂-terminal sequence of Qa-2 in which we have determined the Arg, Leu, His, Phe, Val and Tyr residues within the first 40 amino acids. The sequence of the H-2Kb molecule is also shown. Surprisingly, only 1 of 15 assignments show identity. However, if we assume that during evolution two additional amino acids have been inserted between positions 3 and 7, then shifting the Qa-2 assignments two positions towards the NH₂terminus gives 13/15 assignments which are identical with their H-2K^b counterparts (Fig. 3, bottom). This level of homology confirms the primary structural homology predicted from tryptic peptide map comparisons of Qa-2 and H-2K or -D molecules 11. Further interesting features are: (1) the location of two additional amino acids of Qa-2 on the C-terminal side of position 3 and on the NH2-terminal side of position 7; (2) primary sequence analysis of murine H-2K, -D and -L and their counterparts in other species has shown that the arginines at positions 5, 14, 21 and 35 are highly conserved residues²⁴. Qa-2, on the other hand, has been assigned arginines only at positions 14 and 35 (hereafter we shall refer to the Qa-2 assignments obtained after the 2-amino acid shift). Furthermore, H-2

homologues also show a highly conserved glycine at position 26 (ref. 24); Qa-2 has been assigned a leucine at that position. In addition, Qa-2 lacks a valine at position 9 that is found in H-2Kb, -Kd and -Db molecules. Comparison of the 18 residues (12 assignments, the absence of a valine residue at position 9, and the absence of two arginine residues at 5 and 21) indicates 72-82% homology between Qa-2 and H-2Kb, -Kd, -Db or -Dd. H-2K and -D molecules show 83-94% homology for these 18 positions. These observations indicate that Qa-2 lacks several highly conserved primary structural features of MHCcontrolled major transplantation antigens. Moreover, the Qa-2 alloantigen is rather less related to H-2 alloantigens than they are to each other.

The data therefore suggest that Qa-2 is part of a subfamily of class I gene products, the members of which are distinct at the primary structural and, perhaps, functional levels from members of a second subfamily which includes H-2K, -D and -L. This hypothesis is consistent with the difference between Oa-2 and H-2 antigens with regard to tissue distribution, ontogeny, role as self-recognition units and particularly, extent of polymorphism¹³. Several investigators have postulated that the evolution of polymorphism at H-2 loci was critical for the survival of species/populations against infectious agents^{15,25} The failure of the Qa-2 locus to display extensive polymorphism may indicate a different function for the Qa-2 molecule. Interestingly, tryptic peptide map comparisons of TL with H-2K, -D and Qa-2 indicate that TL is only distantly related to these molecules, which suggests that there may be a third subfamily containing TL (refs 12, 26 and M.J.S., K. McIntyre, J.W.U. and E.S.V., in preparation).

The multigene family encoding class I gene products possibly evolved from a primordial gene that has undergone duplication and subsequent divergence²⁷. The unique primary structural features of Qa-2 suggest that it evolved before H-2K, -D and -L. Furthermore, TL may have diverged before Qa-2 because of the observed modest primary structural homology of TL with Qa-2, H-2K or H-2D (refs 12, 26 and M.J.S. et al., in preparation). Indeed, the unique structural features of the Qa-2 molecule and the finding of Qa and TL homologies in other species perhaps indicate that the Qa-2 and TL duplications occurred before speciation²⁸⁻³⁰. Alternatively, the multiple class I loci may have duplicated at approximately the same time and the observed structural differences evolved as a result of different selective pressures on the individual loci.

We thank Drs Mark Seigelman and J. Donald Capra for advice, discussion and technical support during these studies; Ms Patricia Wheeler and Dr Brad Ozanne for assistance in the two-dimensional gel analysis; Ms Sandy Graham, Shirley Shanahan, Kay Snave and Martha Miles for technical assistance; and Ms Daisi Marcoulides for typing the manuscript. This work was supported by NIH grants AI-13448 and AI-11851.

Mouse immunoglobulin allotypes: post-duplication divergence of γ 2a and γ 2b chain genes

Roger Ollo & François Rougeon

Unité de Génétique et Biochimie du Développement, Institut Pasteur, 28 rue du Dr Roux, 75724 Paris Cedex 15, France

Sequence analysis of the mouse immunoglobulin heavy chain constant-region gene family has provided interesting clues to its evolutionary history1. There are eight genes, each consisting of four exons separated by noncoding sequences, which encode the three globular domains and the small hinge region of the constant-region polypeptide. The eight genes are believed to have arisen by duplications from a single ancestral gene and in particular, the γ 2a and γ 2b genes are thought to have been the result of a recent duplication²⁻⁵. They show, however, a rather surprising pattern of sequence divergence2-7. Schreier et al.7 have reported considerable sequence divergence between the two y2a alleles carried by the BALB/c and C57BL/6 inbred mouse strains; at many of the sites at which the two alleles differ, the BALB/c allele is identical to the BALB/c y2b gene. Thus it has been suggested that the BALB/c γ 2a gene has been converted by the $\gamma 2b$ gene. We have now sequenced the C57BL/6 y2b gene and report that the divergence between the two y2b alleles is very much less than that between the y 2a alleles and is consistent with point mutations. However, it is also clear that the third domain (CH3) of the C57BL/6 y2a gene has diverged so much from the homologous domain in the BALB/c γ 2a gene and the two γ 2b alleles that it may have derived from elsewhere in the heavy chain family and become inserted in the γ 2a gene by a double unequal crossing-over event.

The complete nucleotide sequence of the $\gamma 2b^b$ chain C gene, determined as described in Fig. 1 legend, is shown in Fig. 2. A total of 1,922 nucleotides were determined. The nucleotide sequence predicts the complete amino acid (336 residues) sequence encoded by the $\gamma 2b^b$ allele. We have compared the nucleotide sequence of the $\gamma 2b^a$ allele reported elsewhere⁸ with that of the y2bb allele for over 1,834 positions. As expected for alleles at a single genetic locus, the two sequences exhibit a high level of homology; the pattern of homology is given in Table 1. In the protein-coding regions, the two sequences differ by seven base transitions. There are four G→A transitions which lead to four amino acid substitutions: two located in the CH2 domain $[A \rightarrow G]$ at position 1,083 $(Gln \rightarrow Arg)$ and $A \rightarrow G$ at position 1,175 (Thr→Ala)] and two located in the CH3 domain [A \rightarrow G at position 1,604 (Asn \rightarrow Asp) and G \rightarrow A at position 1,609 (Met → Ile)]. There are three silent substitutions resulting from T o C transitions, one in each domain. Curiously, one of these is located adjacent to the A → G transition, leading to the amino acid change Thr -> Ala in the CH2 domain. It is highly probable that the double transition CA - TG leading to the Thr -> Ala change in the CH2 domain is the result of a double mutation in the y2ba gene as the same TG is found in the two γ 2a alleles.

It is generally assumed that intervening sequences (IVSs) and flanking sequences of a gene evolve more rapidly than the

Table 1 Comparison of nucleotide sequences of BALB/c and C57BL/6 γ2b and γ2a constant-region alleles

protein-coding sequence^{9,10}. It is interesting to note that the noncoding regions of both alleles are highly conserved with respect to size and sequence. There are only three base changes located in IVS1 and IVS2 and one in the 3' genomic flanking region, while the 3'-untranslated region is unchanged. Furthermore, the base deletion located in IVS1 is followed 16 nucleotides downstream by a base insertion, leaving the length of the IVS1 identical in both alleles.

The genetic polymorphism of mouse immunoglobulin in heavy chains has been extensively studied using anti-allotype allosera^{11,12}. However, in only a few cases have the structural basis and the precise location of these polymorphic determinants been determined¹³. By extensive specificity mapping, Herzenberg et al. 11 characterized six alleles at the γ 2b locus, the BALB/c γ 2b^a allele and the C57BL/6 γ 2b^b allele differing by three antigenic specificities. Because of limited amino acid variations between the products of both alleles, it is interesting to correlate the four amino acid differences to allotypic determinants. The first two amino acid changes (Glu \rightarrow Arg, Thr \rightarrow Ala), located in the CH2 domain, are separated by 31 amino acids, and thus are likely to determine separate specificities. A Thr \rightarrow Ala change also occurs in the same region of rabbit γ -chain, allowing the correlation of the A14 and A15 specificities with this amino acid change¹⁴. As the last two amino

acid changes are contiguous, it is reasonable to correlate the third allotypic specificity to the double change Asn-Met→ Asp-Ile (positions 1,604 and 1,609).

From our data and those of Schreier et al.⁷, it appears that the two closely linked $\gamma 2b$ and $\gamma 2a$ chain genes have different rates of evolution (Table 1). Whereas the two $\gamma 2b$ chain alleles differ by only 12 single base changes in 1,850 positions, the two $\gamma 2a$ alleles differ in 111 of 1,093 positions compared. The observation that some of the nucleotides that differ between the two $\gamma 2a$ alleles are conserved between $\gamma 2b$ and $\gamma 2a$ chain genes in BALB/c mice led Schreier et al.⁷ to postulate an intergenic conversion between the two genes. Our data show that these nucleotides are conserved between $\gamma 2a^a$, $\gamma 2b^a$ and $\gamma 2b^b$ genes. Furthermore, these positions are scattered along the sequence and not clustered as in the human fetal γ -globin genes¹⁵. Therefore, if there has been any gene conversion, it could have occurred only in the BALB/c ancestor.

The mutation rate of the $\gamma 2b$ chain gene is as expected for single base mutations in two alleles. However, the mutation rate in the $\gamma 2a$ gene, which is 20 times higher than that in the $\gamma 2b$ gene, is too great to be explained in this way. Note also that most of the differences between $\gamma 2a$ alleles are localized in the CH3 domain. Previous comparative studies of $\gamma 2a$ and $\gamma 2b$ genes led to the hypothesis that segments of the γ genes

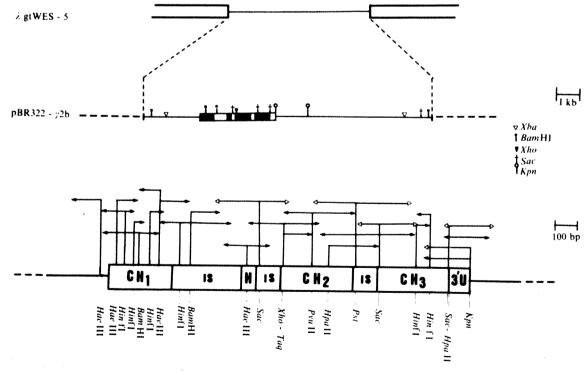

Fig. 1 Sequencing strategy for the mouse γ2b chain constant-region gene. As the γ2b gene lies on a 6.6 kilobase (kb) EcoRI fragment in C57BL/6 mouse embryo DNA¹⁶, EcoRI fragments (fractionated by sucrose centrifugation) ranging in size from 6 to 8 kb were ligated with AgtWES arms purified by gel electrophoresis¹⁷ and packaged in vitro. A hybridization probe consisting of a Xba-Kpn fragment of the BALB/c γ2b gene cloned in phage Charon 4A (unpublished results) was used to isolate a recombinant phage λgtWES-γ2b C57. For sequence analysis, the EcoRI insert was transformed to pBR322. A restriction enzyme map of this insert in pBR322 was determined by single and double digestion of DNA wth various enzymes. The strategy used for sequence determination is shown at the bottom. The extent and direction of sequencing of each fragment are indicated by the horizontal arrows: open and solid arrows represent 3' and 5' end-labelling, respectively. Only the restriction sites used as starting points are shown.

Fig. 2 Nucleotide and predicted amino acid sequences of the C57BL/6 y2b gene. The complete sequence of the DNA fragment containing all the constant regions (CH1, hinge, CH2 and CH3), the three intervening sequences (IVS1, IVS2 and IVS3) and the 5' and 3' flanking sequences is shown. Sequence determination was by the chemical degradation method¹⁸, five base-specific reactions (G, G+A, T+C, A>C) were used. End-labelling was done at the 3' protruding ends using terminal deoxy-nucleotidyl transferase with $[\alpha^{-32}P]$ cordycepin trisulphate, and at the 5' ends by exchange reaction using T4 polynucleotide kinase and $[\gamma^{-32}P]$ -ATP. The numbers below the sequence indicate the positions of the nucleotides. The predicted amino acid sequence of the translated Cy2n protein is shown above the DNA sequence. * The 10 divergent nucleotides found in y2b BALB/c are shown below the homologous bases in the γ 2b C57 sequence. ** Insertion at nucleotide 692 and deletion at nucleotide 708. *** Termination codon.

have been exchanged between different subclass genes^{4,5}. As there is extensive divergence between the γ 2b and γ 2a CH3 domains and between the two allelic γ 2a CH3 domains, we suggest that the γ exons encoding γ 2a CH3 domains could have diverged on ancestral y-like genes before the y2b/y2aduplication. These exons, originally duplicated on a single chromosome, could behave as alleles as a result of different recombinational events (IVS-mediated transfer hypothesis or unequal crossing-over^{4,5}) in different mouse strains.

We therefore conclude from sequence analysis of the mouse γ -chain genes that the divergence rate between two homologous genes can be either accelerated or reduced by gene interchange: domain transfer increases genetic diversification while gene conversion maintains genetic stability.

We thank R. Nageotte for the C57BL/6 embryo DNA preparation; W. Roskam for the gift of \(\lambda\) gtWES arms; M. J. Singer, Mrs A. Minty and H. Eisen for critical reading of the manuscript; and B. Caudron for the computer program. This work was supported by grants from the CNRS (A.T.P. 3663 and 4247) and the Fondation pour la Recherche Médicale Francaise.

A sex-linked enzyme in birds— **Z-chromosome conservation** but no dosage compensation

P. R. Baverstock*, M. Adams*, R. W. Polkinghorne† & M. Gelder*

* Laboratory Animal Services, Institute of Medical and Veterinary Science, Frome Road, Adelaide, South Australia 5000 † Parafield Poultry Research Centre, Department of Agriculture, PO Box 3, Salisbury, South Australia 5108

In birds, the female is the heterogametic sex and the sexdetermining system is referred to as ZZ/ZW. In mammals the male is heterogametic, and the sex-determining system is referred to as XX/XY. The mammalian X chromosome appears to have been conserved largely intact during evolution. Thus the structural gene loci for glucose-6-phosphate dehydrogenase, phosphoglycerate kinase, α-galactosidase and hypoxanthine-guanine phosphoribosyltransferase are situated on the X chromosome of a wide variety of mammals. In addition, mammals show 'dosage compensation'; that is, although females possess two doses of each X-linked gene while males possess only one, females produce the same level of gene product as males. In birds, cytological studies and data on sex-linked morphological mutants suggest that the Z chromosomes of all birds are homologous, and that birds do not show dosage compensation for sex-linked genes. Ultimate proof of these hypotheses requires the discovery of proteins whose structural gene loci are encoded by the Z chromosome of birds1, none of which has previously been found. Here we report that the cytoplasmic isozyme of aconitase is Z-linked in the guinea fowl and probably Z-linked in the domestic fowl, house sparrow and two species of cockatoos, thereby providing evidence for Z-chromosome homology in birds. We also show that there is an apparent lack of dosage compensation for cytoplasmic aconitase in the domestic fowl, house sparrow and spotted turtledove.

Electrophoresis was conducted on Cellogel², and aconitase made visible by the method of Harris and Hopkinson³. Using this system, two zones of aconitase activity are found in bird liver. By differential centrifugation of mitochondrial and cytoplasmic fractions it was shown that the more anodally migrating zone of activity was the cytoplasmic fraction (Fig. 1). The cytoplasmic isozyme of aconitase (Acon_c) from liver of the guinea fowl (*Numida meleagris*—order Galliformes) migrates more anodally than that of domestic fowl (*Gallus domesticus*—order Galliformes) (Fig. 1). We denote the domestic fowl form of Acon_c as A and that of the guinea fowl as B. Hybrids between guinea fowl and domestic fowl were produced by artificial insemination⁴.

If the structural gene for Acon_c were autosomal, all offspring from such a cross would be heterozygous AB. If, however, the locus for Acon_c were on the Z chromosome, male offspring would be heterozygous AB whereas female offspring would be hemizygous A or B depending on the direction of the cross.

Crosses between female guinea fowl and male domestic fowl yielded hybrid embryos most of which died within the first week of incubation. A small number survived for longer periods, including one that survived to hatching. A total of 17 embryos were successfully typed for aconitase and of these, five were of known sex either from gonad histology or karyotyping⁵. Seven of the embryos were AB but ten were A (Table 1). Moreover,

Table 1 Cytoplasmic aconitase types of hybrid embryos between female guinea fowl (type B) and male domestic fowl (type A)

***************************************			******
		Acon _c type	
	Α	AB	В
Male embryos	0	3	0
Female embryos	2	0	0
Unsexed embryos	8	4	0
Total	10	7	0

of the five embryos of known sex, the three males were AB and the two females were A (Table 1 and Fig. 1). The results therefore indicate that the locus for Acon_c is not autosomal in the guinea fowl, but is located on the Z chromosome.

The data do not exclude the possibility that Acon_c is autosomally inherited in domestic fowl and sex-linked in guinea fowl. Crosses between female domestic fowls and male guinea fowls yielded embryos that died within 24 h. Aconitase activity was undetectable in most of these embryos. However, three embryos yielded a faint band of aconitase activity in the position of guinea fowl Acon_c and no detectable activity in the position of domestic fowl Acon_c. These results are expected for female hybrid embryos if Acon_c is encoded by a locus on the Z chromosome of the domestic fowl, and suggest therefore that Acon_c is Z-linked in the domestic fowl also.

We have found that Acon_e is polymorphic in three species of birds—the little corella, *Cacatua sanguinea* (order Psittaciformes), the yellow-tailed black cockatoo, *Calyptorhyncus funereus* (order Psittaciformes), and the house sparrow *Passer domesticus* (order Passeriformes).

Table 2 shows the observed phenotype frequences for Aconin little corellas from Three Springs, Western Australia. Of five males, two were type F (fast migrating band) and three were type FS (double banded fast and slow), whereas of 12 females, nine were type F and three were type S (Table 2). No heterozygous females were found. The appropriate statistical test is to construct a 2×2 contingency table for heterozygote and homozygote males versus females. Applying Fisher's exact probability, P is 1.5%. The absence of heterozygous females is therefore statistically significant. If we take the gene frequencies for males and calculate expected phenotype frequencies for females on the hypothesis that $Acon_c$ is sex-linked, the fit to the observed results is then excellent (Table 2), suggesting that the locus for $Acon_c$ is on the Z chromosome of C. sanguinea.

In five yellow-tailed black cockatoos (two males and three females) from Bool Lagoon, South Australia, three alleles for Acon_c were found, designated F, I and S (fast, intermediate and slow). One male was heterozygous FI, and the other was heterozygous IS, but of the three females, one was single-banded F, one was single-banded I and the third was single-banded S. Again these data are more consistent with the locus for Acon_c being on the Z chromosomes of *C. funereus* than on an autosome.

Samples of house sparrows (*P. domesticus*) from Adelaide, Canada and the UK were also polymorphic for Acon_c (data for Canada and UK from S. R. Cole and D. Parkin, personal communication). Again there was an absence of heterozygous females which is highly significant statistically in the UK sample, and significant at the 5% level in the Canadian sample (Table 2). The observed phenotype distributions for females are, on the other hand, consistent with the locus for Acon_c being on the Z chromosome of *P. domesticus*.

Ohno¹ has suggested that the Z chromosome has been conserved during evolution of the class Aves; thus any gene that is on the Z chromosome of one species of bird should be found on the Z chromosome of all bird species. The present study has shown that Acon_c is on the Z chromosome of a galliform and probably on the Z chromosome of another galliform, two psittaciforms and a passeriform. These data provide support for Ohno's hypothesis and suggest that Acon_c is on the Z chromosome of all birds. The data do not prove, however, that the entire Z chromosome has been conserved, rather that part of the Z chromosome carrying the structural locus for Acon_c has been conserved.

Ohno¹ also suggested that the Z chromosome of birds may be homologous with the X chromosome of mammals. Clearly, this is not the case. The enzymes glucose-6-phosphate dehydrogenase and phosphoglycerate kinase are sex-linked in

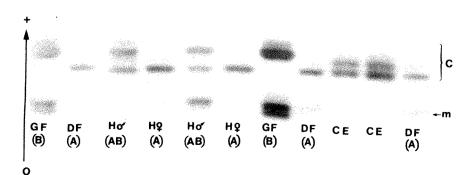

Fig. 1 Electrophoretic gel stained for aconitase. O, origin; m, mitochondrial fraction (Acon_m); C, cytoplasmic fraction (Acon_c); GF, guinea fowl (type B for Acon_c); DF, domestic fowl (type A for Acon_c); H, hybrid between female guinea fowl and male domestic fowl; CE, cytoplasmic extract of chicken liver after differential centrifugation to remove the mitochondrial fraction. Note that the proposed heterozygotes are double-banded, indicating that avian cytoplasmic aconitase is monomeric as in mammals³. The weaker secondary bands result from post-translational modification.

mammals but not birds⁶. Acon_c, on the other hand, is sex-linked in birds, but not mammals³.

Because Acon_c is Z-linked in birds, males have two doses of the gene and females one dose. Therefore in the absence of dosage compensation, male birds will possess twice the activity of cytoplasmic aconitase of females. We have measured the level of cytoplasmic aconitase activity in the livers of 1-day-old chickens, mature house sparrows and mature spotted turtle-doves (Streptopelia chinensis—order Columbiformes). In all three species, females had statistically significantly lower levels of cytoplasmic aconitase activity than males (Table 3). On the

other hand, where the null hypothesis was tested that males possess twice the activity of females, non of the P values were statistically significant (Table 3). That such a result was not due to generally lower enzyme activity in females was shown by comparing the levels of isocitrate dehydrogenase (IDH) activity in the same cytoplasmic fractions. In all three species, males and females did not differ significantly with respect to IDH activity. It is clear, therefore, that the locus for Acon_c does not show total dosage compensation in birds.

Dosage compensation of all but one or two X-linked genes in mammals is effected by inactivation in each cell of one of

Livers were removed from freshly killed individuals and placed in twice their weight of cold homogenizing solution (0.25 M sucrose, 0.001 M EDTA in 0.1 M Tris-HCl pH 7.8). The tissues were homogenized by hand and centrifuged at 10,000g at 4 °C for 25 min. The supernatant was removed and stored frozen at -80 °C. Electrophoresis of the supernatant revealed only a trace of the mitochondrial isozyme of aconitase (Fig. 1). Aconitase activity in the supernatant was assayed by a modification of the method of Ruse and O'Connell¹⁰, isocitrate dehydrogenase activity by the method of Cleland¹¹, and total protein by the method of Lowry¹². Values are mean ± s.d. µmol NADP converted per min per mg protein. N, number of individuals.

the X chromosomes?. In Drosophila most genes on the X chromosome are dosage-compensated, but here each gene on the X chromosome produces half the amount of product in females as in males8. However, not all genes on the X chromosome of Drosophila show complete dosage compensation. Therefore the observation that Acon, shows no dosage compensation in birds should not be taken as proof that all Z-linked genes in birds show no dosage compensation. Nevertheless, when taken in conjunction with the morphological data1, the present data suggest that lack of dosage compensation is the rule in birds. As pointed out by Johnson and Turner⁹, it may be no coincidence that the groups known to show dosage compensation (mammals and Drosophila) have XX/XY sex determination while the groups lacking dosage compensation (lepidopterans and birds) have ZZ/ZW sex determination.

Evidence for X-linkage and non-inactivation of steroid sulphatase locus in wood lemming

H-H. Ropers

Institut für Humangenetik und Anthropologie, Albertstrasse 11, D-7800 Freiburg i. Br., FRG

U. Wiberg

Institute of Genetics, University of Lund, Sölvegatan 29, S-223 62 Lund, Sweden

One of the two X chromosomes is inactivated in somatic cells of adult female mammals to compensate for unequal amounts of X-chromosomal genes in the two sexes1. Although the general validity of this concept is not in doubt, there is evidence that a segment of the distal short arm of the human X chromosome carrying the gene, or genes for the Xg blood group system, the steroid sulphatase (STS) locus^{2,3}, and a gene controlling a serologically defined male-specific antigen^{4,5}, is never inactivated. It is not known whether this non-inactivated segment is a special feature of the human X chromosome or whether it is a general feature of the ancestral, highly conserved, mammalian X chromosome⁶. In man the number of functional STS gene copies can be deduced from intracellular STS activity7. With this in mind we have investigated the number of active gene copies on the X chromosome of the wood lemming (Myopus schisticolor, Lilljeborg), by assaying STS in cultured cells of this species. We report here that STS activity is directly correlated to the number of X chromosomes and unrelated to the phenotypic sex. This suggests that in the wood lemming the STS gene is also X-linked and not subject to inactivation.

The remarkable stability of the mammalian X chromosome can be explained, in part, by the fact that males carrying X-autosomal translocations are mostly sterile. This is thought to result from a failure of inactivation of translocated X-chromosome segments during gametogenesis⁸. As a result, Xautosomal translocations cannot be transmitted through males, and therefore do not spread in the population. This notion suggests that strict evolutionary conservation may be confined to those parts of the X chromosome that are subject to inactivation, as males with translocations involving permanently active segments would not necessarily be sterile. In man the existence of a non-inactivated segment on the distal short arm of the X chromosome is now well established9. For one of the three genes assigned to this region (that is, the STS gene), in both sexes, significant differences in enzyme activity have been demonstrated for various cells and tissues such as fibroblasts, hair roots and placenta^{7,10,11}. Similar gene-dosage relationships have been observed in numerical, and most structural, Xchromosomal aberrations¹²

In the wood lemming, numerical sex chromosome aberrations are relatively frequent due to its unique system of sex determination. There are two different types of X chromosome, X and X*, which can be distinguished cytogenetically¹³. Specimens with XX, X*X, X*Y, XO and X*O sex chromosome constitutions are phenotypic females and are fertile. Males have the XY sex chromosomes^{13,14}. In germ-line cells of X*Y females only the X* chromosome is found. By a mechanism of mitotic double non-disjunction, the Y chromosome is replaced by a copy of the X* (refs 15, 16). The relatively high incidence of numerical sex chromosome aberrations probably depends on occasional failure of this non-disjunction mechanism.

The molecular basis of sex reversal in X*Y females is not yet understood. The fact that the X* differs from the X both morphologically and functionally suggests that this may be due to duplication or deletion of genes involved in sex differentiation. In man, a gene or genes controlling sex differentiation may be closely linked to the STS locus on the non-inactivated distal part of Xp^{4,5,17,18}. To determine whether in a rodent species the STS gene is also X-linked and not inactivated, and whether the dosage of this gene is altered on the rearranged X*, we have determined STS activity in cultured fibroblasts from wood lemmings of seven different sex chromosome constitutions.

Primary fibroblast cultures were established from heart tissues in Earle's modified Eagle's minimal essential medium supplemented with 15% fetal calf serum. After karyotyping and two or three further passages in culture, the cells were analysed biochemically. In three subsequent series of experiments, a total of 54 cultures, representing 27 wood lemming specimens, were tested for STS activity; 30 cultures were also assayed for an X-linked reference enzyme, that is, glucose-6phosphate dehydrogenase (G6PD).

STS activities were found to be directly correlated with the number of X chromosomes, irrespective of the phenotypic sex (Table 1) while no such correlation was found for G6PD (Table 2). The simplest interpretation of these results is that in the wood lemming, as well as in man, STS is X-linked and not subject to X-inactivation. Therefore, we suggest that the STS gene may be part of the conserved X-chromosomal linkage group of mammals, although this has yet to be confirmed in other mammalian species. Conservation of a permanently active segment of the mammalian X chromosome could be related to the hypothesized homology between this segment and part of the Y chromosome^{19,20} for which there is now increasing, although circumstantial, evidence^{17,18,21}. It is noteworthy that in man, genes on this segment have been implicated in sex determination^{4.5,17,18}, suggesting that sex reversal in the wood lemming may be due to altered dosage of related genes on the rearranged X*. While this possibility cannot be excluded, the observation that STS levels are almost identical in wood lemming specimens, whether they carry the normal X or the altered

STS activity is expressed as pmol dehydroepiandrosterone sulphate cleaved per mg protein per h. For determination of STS, early confluent cells were collected with trypsin, washed twice in Hank's balanced salt solution, suspended in lysis buffer (5 mM Tris-HCl, 2 mM EDTA, 7 mM mercaptoethanol, 0.1% Triton X-100 pH 7.5) and sonicated using a Branson sonifier with microtip (4×5 s, 50 W). ³H-dehydroepiandrosterone sulphate (DHEAS, specific activity 24 mCi μ mol⁻¹; NEN) was diluted with cold DHEAS to a specific activity of 10μ Ci μ mol⁻¹, then extracted three times with diethyl ether to remove free dehydroepiandrosterone. 10μ l of this solution, corresponding to 10μ 0 nmol DHEAS, were incubated at 37 °C for 2μ 1 with 50μ 1 of homogenate and 50μ 1 of 0.1μ 1 M Tris-HCl buffer pH 7.5, containing 10μ 2 mg bovine serum albumin (BSA) per ml. Then 0.1 ml of 0.2 M NaOH and a 10-fold excess of cold DHEAS were added, followed by extraction with 3 vol of ether. An aliquot of the ether phase was evaporated to dryness, and radioactivity determined by scintillation counting²². Blank controls contained lysis buffer with 10 mg ml⁻¹ BSA instead of homogenate. The relationship between STS activity and protein concentration is linear $(r = 0.99 \pm 0.07)$ up to 800 µg of protein. Mean enzyme levels can vary in subsequent tests due to non-saturating substrate concentrations in the assay. Each value represents the mean of two independent cultures which were each tested in duplicate

Cultures not confluent. † Sterile male. ± Confluent cultures only.

X* chromosome, strongly argues against a duplication or deletion of the STS locus on the abnormal X*. It follows that, in this species, either the STS gene is not closely linked to gene(s) responsible for sex reversal, or the two genes have been separated by rearrangement on the aberrant X* chromosome.

Transposition of a tandem duplication of yeast mating-type genes

James E. Haber & David T. Rogers

Rosenstiel Basic Medical Sciences Research Center and Department of Biology, Brandeis University, Waltham, Massachusetts 02254, USA

The switching of mating-type genes in both homothallic and heterothallic strains of the yeast Saccharomyces cerevisiae involves a site-specific transposition event1-3. A sequence at the mating-type locus (MAT) is replaced by a copy of a or α information from the unexpressed loci, HML or HMR. Although MATa and MATa contain unique sequences of ~700 base pairs (bp), they are flanked by sequences that are also found at HML and HMR4.5 (Fig. 1a). Recent results6-8 have suggested that the switching of \overline{MAT} alleles involves an intrachromosomal mitotic gene conversion event, in which a donor sequence at HML or HMR pairs with the homologous sequences at the MAT locus. On this view the switching of mating-type information must be able to accommodate the region of non-homology in a heteroduplex structure. (Analogous gene conversions of non-homologous regions have been well documented during meiosis at MAT and for deletions in other yeast genes^{9,10}.) One prediction of a gene conversion mechanism is that it should be possible to transpose a tandem duplication of mating-type genes from HMR to MAT. In such a switch, pairing would occur between MAT and homologous sequences flanking the two copies of the tandem duplication at HMR. Our results reported here demonstrate that a tandem duplication created at HMR by recombinant DNA techniques can be transposed to MAT without the loss of these sequences at the donor locus.

Tandem duplications of mating-type genes at HMR were constructed by transforming the heterothallic (ho) strain DB 745 (HML\alpha MAT\alpha HMR\alpha ura3-52 leu2 ade1) with plasmid pDRMATa3, which contains the 3.5 kilobase (kb) EcoRI-HindIII MATa fragment and the 1.1 kb HindIII URA3 fragment inserted into pBR322 (Fig. 1a). In 3 of 20 Ura+ transformants the plasmid had integrated at HMR. These were shown by Southern blot analysis to be two types. In DR103 and DR107 a single copy of the plasmid was inserted, generating the structure HMR::(MATa-URA3-pBR322) (Fig. 1b). At least one of the two fusions between MAT and HMR sequences expressed a information, so that the $MAT\alpha$ cell was phenotypically non-mating. The third transformant had two copies of the plasmid tandemly inserted. generating the structure HMR: $(MATa-URA3-pBR322)_2$ (Fig. 1c). Again, at least one of the a-containing regions expressed a information; thus strain DR204 was also non-mating. We have also obtained an insertion of pDRMATa3 at MATa, giving the structure MATa-URA3-pBR322-MATa (strain DR212, Fig. 1d). This duplication has the structure expected for the transposition of a tandem duplication for HMR::(MATa-URA3-pBR322).

Figure 2a shows an example of the Southern blot analysis used to confirm these structures. A BamHI digest of DNA from the transformants was probed with labelled pDRMATa3 (Fig. 2a, lanes 1-4) or with labelled pBR322 (lanes 5-8). Because there is only a single BamHI site in pDRMATa3 (Fig. 1), one would expect a single integrant of the plasmid to yield two BamHI fragments, one of which should hybridize strongly with pBR322, and the other, homologous to only 300 bp (Fig. 1b), weakly. This was indeed the case for DNA from transformants DR103 and DR107 (Fig. 2a, lanes 6, 7). The third transformant, DR204, gave rise to the same BamHI fragments plus one strongly hybridizing fragment the same size as the original plasmid (Fig. 2a, lane 8). This is consistent with the HMRa::(MATa-URA3-pBR322)₂ structure shown in Fig. 1c. The tandem duplication at MAT (strain DR212) results in differently sized BamHI fragments (Fig. 2a, lane 1).

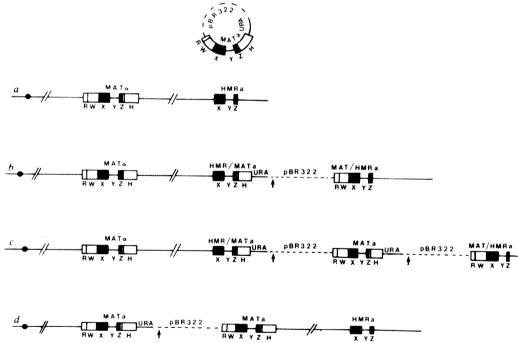

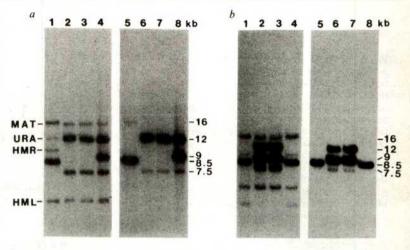

Fig. 1 Structures generated by the integration of plasmid pDRMATa3 by homologous recombination at HMRa or MATa. The plasmid contains the 3.5 kb EcoRI-HindIII fragment including MATa and the 1.1 kb HindIII fragment of URA3. a, The regions of homology between the plasmids and HMRa are indicated as solid blocks (X, Y and Z, according to ref. 5). The regions of homology between the plasmid and MATa are shown by the open and solid blocks [the W region plus the adjacent segments extending to the EcoRI site (R) and the HindIII site (H)]. The HMLa locus on the left arm of the chromosome (not shown) shares with MAT the homology regions W, X and Z. The Ya region at MATa is not homologous to Ya in the plasmid or at HMRa. The pBR322 sequences are indicated as ---. BamHI sites in pBR322 used to analyse the structure of the transformants are shown by arrows. b, A single integration of the plasmid at HMRa (strain DR103 and DR107). c, A tandem insertion of the plasmid at HMRa (strain DR204). d, Insertion of the plasmid at MATa (strain DR212).

Fig. 2 Southern blot analysis of a transposition of a tandem duplication of a-mating-type sequences from HMRa::(MATa-URA3)₂ to replace MATα. a, Analysis of insertions of pDRMATa3 at HMRa and MATa. DNAs from four strains, described below, were digested eith BamHI, separated by agarose gel electrophoresis and the Southern blot probed with either labelled pDR MATa3 (lanes 1-4) or labelled pBR322 (lanes 5-8). Lanes 1, 5: strain DR212 (Fig. 1d), MATa::(MATa-URA3); lanes 2, 6: strain DR103 (Fig. 1b), HMRa::(MATa-URA3); lanes 3, 7: strain DR107 (Fig. 1b), HMRa::(MATa-URA3); lanes 4, 8: strain DR204 (Fig. 1c), HMRa::(MATa-URA3)2. The identity of each band was determined by additional hybridizations with DNA probes specific for URA3, MAT and HML (data not shown). Two BamHI fragments of 12 kb and 7.5 kb are generated when pDRMATa3 integrates at HMRa (see Fig. 1b and lanes 2, 3, 6, 7). A tandem insertion of the plasmid at HMRa creates the same two BamHI fragments, plus a 9 kb fragment identical in size to the plasmid (see Fig. 1c and lanes 4, 8). Creation of a tandem duplication at MATa (by the integration of plasmid pDRMATa3 at MATa) creates two RamHI fragments of 16 and 8.5 kb, both of which hybridize to labelled pBR322. b, Southern blot analysis of four meiotic segregants from a diploid (DR204/A145 no. 2) of genotype:

HMLα MATa URA3 pBR322 MATa HMRa::(MATa-URA3)₂ HMLα MATα HMRa

DNA from each of four segregants was cut with BamHI and the separated fragments probed with labelled pBR322 (lanes 1-4) or pDRMATa3 (lanes 5-8). Two of the segregants were a-mating and Ura⁺, and carry MATa sequences derived by transposition from $HMRa::(MATa-URA3)_2$. These two strains (lanes 1, 4; lanes 5, 8) contain BamHI fragments characteristic of a tandem duplication at MATa (see Fig. 2a, lanes 4, 8). The other two segregants (lanes 2, 3; lanes 6, 7) were non-mating, Ura⁺ and carry MATa as well as a information expressed at $HMRa::(MATa-URA3)_2$. The BamHI fragments are identical in size to those in the original parent strain, DR204 (Fig. 2a, lanes 3, 7).

Transposition of copies of a information HMRa::(MATa-URA3-pBR322) was monitored by crossing the non-mating Ura+ strains with strain A145 (ho MATa ura3 leu1 ade1) and selecting Ura+ diploids. These could only arise if the non-mating strains became a-mating by the transposition of a information from the tandem duplication at HMR to replace $MAT\alpha$. Ten diploids from each of the three mating experiments were analysed by tetrad analysis to determine whether the conversion of the MATα HMRa::(MATa-URA3-pBR322) strain to MATa resulted from an event that also transposed a copy of the URA3 gene (see Table 1). In all 20 cases involving strains DR103 and DR107 the segregation of markers indicated that a single copy of MATa had been transposed to the MAT locus without URA3—that is, the expression of an a mating type was not linked to URA3 and each tetrad contained two Ura+ and two Ura- segregants. If there were two unlinked URA3 genes segregating in these cases, the probability of finding a 2+:2- tetrad would be only 1/6. Furthermore, there were an equal number of α -mating Ura strains and non-mating Ura segregants, presumably carrying $MAT\alpha$ and either HMRa or HMRa::(MATa-URA3-pBR322) respectively. In contrast, in two of the ten diploids isolated from mating strain DR204 with A145 there was a second copy of URA3 segregating in the cross and one copy of URA3 was tightly linked to MATa. This is evident from the fact that most tetrads contained three or four Ura segregants per tetrad and that every a-mating segregant was Ura⁺. Half of the $MAT\alpha$ segregants were Ura⁺ and non-mating. We concluded that in two of the ten transpositions of a information from HMRa:: (MATa-URA3-pBR322)2 in strain DR204 the transposition event also mobilized the URA3 gene.

Using Southern blot analysis to study one transposition event (DR204/A145 no. 2), we have shown that (1) the transposition did indeed create a tandem duplication of *MATa* flanking *URA3* and pBR322 at *MAT*; and (2) that the structure at the donor *HMRa*::(*MATa-URA3*-pBR322)₂ locus was not altered (see Fig. 2b). DNA was isolated from one tetrad of diploid DR204/A145 no. 2 in which all four segregants were Ura⁺. A Southern blot of DNA digested with the restriction endonuclease *BamHI* was probed with labelled pDR*MATa3* (Fig. 2b, lanes 1-4) or pBR322 (lanes 5-8). The two segregants that were a-mating and Ura⁺ contained two new bands (16 and 8.5 kb) characteristic of an insertion of the *MATa-URA3*-pBR322 plasmid at *MATa* (lanes 1, 4). The other two

segregants which were non-mating and Ura⁺ were shown to carry $MAT\alpha$ and the pair of 7.5 and 12 kb BamHI restriction fragments found with the $HMR::(MATa-URA3-pBR322)_2$ duplication of the parent strain DR204 (lanes 2, 3). These data confirm that the transposition event created a tandem duplication of MATa and transposed the intervening URA3 and pBR322 sequences.

These experiments show that the mechanism of switching MAT genes can transpose a tandem duplication of mating-type genes and 5.5 kb of non-homologous intervening sequences. If the evidence favouring a gene conversion model for MAT switching is correct, even the transposition of a single copy of a to replace $MAT\alpha$ must form a heteroduplex in which the non-homologous sequences of a- and α -specific DNA are not paired. In the case where a tandem duplication of MAT genes was transposed, we presume that a heteroduplex formed between homologous sequences (W and Z) on the outside

Table 1 Heterothallic conversions of $MAT\alpha$ to MATa or to MATa-URA3-pBR322-MATa

Heterothallic non-mating strains DR1203 and DR107 (ho, MAT α , HMRa::(MAT α -URA3-pBR322)) and strain DR204 (ho, MAT α , HMRa::(MATa-URA3-pBR322) $_2$) were crossed with the MAT α HMRa ura3 strain A145. Ten independent rare matings of each cross were purified, sporulated and analysed by tetrad dissection. The total numbers of each type of tetrad are shown. Non-mating segregants are designated NM.

^{*} Sum of 10 independent diploids analysed.

[†] Sum of eight independent diploids analysed.

Fig. 3 A model for the transposition of a tandem duplication of mating type genes from HMR::(MATa-URA3-pBR322)2 to replace MATa. A gene conversion event in which sequences at HMR are used to replace non-homologous sequences at MAT first requires the homologous pairing of these regions, as shown. Instead of the normal 0.7 kb region of non-homology transferred between HMRa and MATa, the pairing of the outside homologous regions of the tandem duplication at HMRa::(MATa-URA3pBR322)2 leads to the insertion of a 7.9 kb region of DNA not homologous to $Y\alpha$.

portions of two different donor sequences (Fig. 3) could then create a large non-homologous region in the middle of the heteroduplex. DNA mismatch repair favouring the incoming strand would then allow the entire region to be transposed. It is significant that we found such transpositions with strain DR204 but not with strain DR103 or DR107. One explanation for this difference is that the extent of homologous pairing that can be formed, especially on the right side of the unique sequences, is substantially greater (1.1 kb compared 0.23 kbusing the multiple tandem cation HMRa::(MATa-URA3-pBR322)2 than the single HMRa::(MATa-URA3-pBR322) integrant. The greater homology may stabilize the unusually large non-homologous region in a heteroduplex structure.

We have recently also carried out a complementary study of the switching of a tandem duplication of MAT genes at the mating-type locus (J.E.H. and D.T.R., in preparation). Homothallic strains carrying a $MAT\alpha$ duplication switched efficiently and usually the tandem duplication was replaced by a single MATa locus. Pedigree studies have shown that the loss of the duplication and the switch to the opposite mating type occurs during a single cell division. Analogous to our interpretation of transposition of a duplication from HMR to MAT (Fig. 3), we explain the complementary study by supposing that the donor HMRa must pair with the common region X, to the left of one $MAT\alpha$ gene and the common region Z1 on the right of the other $MAT\alpha$ locus. A gene conversion would then replace a large (7.9 kb) non-homologous sequence with the 0.7 kb unique a sequence.

We believe our results are consistent with an intrachromosomal gene conversion mechanism for switching mating type.

This research was supported by USPHS grant GM20056. We thank Barbara Weiffenbach for her comments on the manuscript. D.T.R. was a Charles A. King Trust Research Fellow.

Induction of a DNA glycosylase for N-methylated purines is part of the adaptive response to alkylating agents

Peter Karran*, Thomas Hjelmgren† & Tomas Lindahl*

* Imperial Cancer Research Fund, Mill Hill Laboratories, Burtonhole Lane, London NW7 1AD, UK

Department of Medical Biochemistry, Gothenburg University, Gothenburg, Sweden

The resistance of Escherichia coli to simple alkylating agents, for example N-methyl-N'-nitro-N-nitrosoguanidine (MNNG), is markedly increased in cells previously exposed to low doses of the agents. This adaptive response seems to reflect improved repair of alkylation lesions in DNA, and cells become less sensitive to both the mutagenic and killing effects of alkylating agents^{1,2}. Adaptation to the former is due largely to the induction of a repair function that removes O6-methylguanine (m⁶G) from DNA^{3,4}. This activity has been purified from induced cells and is attributed to a protein that transfers the methyl group of an m6G residue in DNA to one of its own cysteine residues5. Consequently, no excision of damaged nucleotide residues seems to be necessary. The adaptive response to killing by alkylating agents, however, is less understood. DNA excision-repair with gap-filling catalysed by DNA polymerase I seems to occur as part of the inducible response, as it depends on the presence of a functional polA+ gene2 and enhanced DNA polymerase I-mediated repair synthesis has been observed in adapted cells challenged with MNNG6. Here we show that the adaptive response involves induction of not only a methyltransferase for m6G, but also a DNA glycosylase that catalyses the release of purines methylated at ring nitrogen atoms. We also identify the minor alkylation product 3-methylguanine (m3G) as an important lethal lesion.

One of the major methylation products in DNA, 3-methyladenine (m3A), is known to be actively and rapidly removed in vivo 7.8. The enzyme responsible, 3-methyladenine DNA glycosylase I, can easily be detected in extracts from unadapted cells, and it seems to be constitutively expressed. This activity has been extensively purified and characterized9. The enzyme, which has a molecular weight of about 19,000, shows a very narrow substrate specificity and of several different DNA methylation products, only m3A is released from methylated DNA. E. coli mutants (tagA) deficient in this enzyme have been isolated, and although they are less able to remove m3A from their DNA after exposure to alkylating agents8, they are not totally deficient in m3A DNA glycosylase activity. The

Table 1 DNA glycosylase activities in various E. coli strains before and after adaptation by MNNG treatment

		Specific acti extract (µ	
E. coli strain	DNA Glycosylase	Unadapted	Adapted
E. coli B/r	Uracil	3,800	3,500
	Hypoxanthine	2.1	2.0
	3-Methyladenine I	3.6	3.6
	3-Methyladenine II	0.22	4.1
	3-Methylguanine	~0.05	1.1
	7-Methylguanine	~0.02	0.2
	Formamidopyrimidine	4.2	3.9
	Thymine glycol	1.9	1.7
	Urea	5.5	4.8
E. coli BK2114	3-Methyladenine I	< 0.02	< 0.1
(tagA)	3-Methyladenine II	0.20	7.8
	3-Methylguanine	~0.05	1.7
	7-Methylguanine	~0.02	0.4

E. coli cells were adapted by growth in MNNG (1 μg ml⁻¹) for 60 min. The uracil, hypoxanthine, formamidopyrimidine, thymine glycol and urea DNA glycosylases were assayed in cell-free extracts as described previously^{13,22-25}. The products released by m³G, m⁷G and m³A DNA glycosylases from ³H-dimethylsulphate-treated DNA were characterized by HPLC as described in Fig. 2 legend.

residual function, which represents 5-10% of the total activity in wild-type cell extracts, has properties different from m³A DNA glycosylase I: it is resistant to product inhibition by free m³A; it is relatively heat resistant; and it is present in similar amounts in wild-type cells and in *tagA* mutants. It has therefore been concluded that the minor activity is a separate enzyme, which has been termed 3-methyladenine DNA glycosylase II^{8.10}.

When the enzymatic release of free m3A from alkylated DNA was measured, using cell extracts from unadapted and adapted E. coli, the adapted cells exhibited two- to threefold more DNA glycosylase activity. To assess the relative contributions of m³A DNA glycosylases I and II, the cell extracts were chromatographed on Sephadex G-75, and column fractions assayed in the presence and absence of m³A (3 mM). In these conditions, m³A DNA glycosylase I is 90-95% inhibited whereas enzyme II is not affected. Figure 1a shows that enzyme II accounted for 5-10% of the total enzyme activity in extracts of unadapted cells, in agreement with previous results8. In adapted cells, however, this enzyme was responsible for 50-70% of the total activity (Fig. 1b). Thus, although there was no detectable difference between the levels of m³A DNA glycosylase I in adapted and unadapted cells, m³A DNA glycosylase II was present at a 20-fold higher level in adapted cells. This induced activity was eluted before the constitutively expressed enzyme I on Sephadex G-75 (Fig. 1b), indicating a higher molecular weight of enzyme II.

The identity of the induced enzyme as m³A DNA glycosylase II was confirmed by experiments with an E. coli tagA mutant (BK2114), which lacks enzyme I. In this strain, the level of m³A DNA glycosylase activity was low, but could be induced 20- to 40-fold by exposure to MNNG (Table 1). The induced activity was resistant to inhibition by free m³A, as expected for enzyme II, and also exhibited the heat stability of enzyme II. The separate identities of enzyme I and the inducible enzyme II is further supported by the observation of Evensen and Seeberg that E. coli alk mutants are deficient specifically in the latter enzyme11. In agreement with previous studies of the adaptive response², MNNG was a good inducer of m³A DNA glycosylase II, whereas methyl methanesulphonate was less efficient and 4-nitroquinoline-1-oxide had no effect. An E. coli strain (BS21) which expresses the adaptive response constitutively and contains high levels of the methyltransferase acting on m⁶G (ref. 12), did not contain a similarly elevated amount of m³A DNA glycosylase II, although it had slightly more (twoto threefold) enzyme than did unadapted wild-type cells.

In addition to the increased release of m^3A from alkylated DNA, extracts from adapted cells were also active on other N-methylated purines in DNA. Thus, whereas only extremely low levels of DNA glycosylase(s) which released m^3G and 7-methylguanine (m^7G) from methylated DNA were detectable in extracts of unadapted cells, such activities were easily demonstrable in crude extracts of adapted cells (Fig. 2, Table 1). Even in the latter extracts, however, m^7G DNA glycosylase activity was quite low; in assay conditions which resulted in complete release of m^3A and m^3G from methylated DNA, only $\sim 0.3\%$ of the m^7G was enzymatically released.

Several other DNA glycosylases, which specifically recognize different types of damaged bases in DNA, have been found in E. coli. A survey of the levels of these activities in extracts from unadapted and adapted cells showed that only m³A DNA glycosylase II, m³G DNA glycosylase and m³G DNA glycosylase activities were induced during adaptation by MNNG treatment (Table 1). Note that the amount of formamidopyrimidine DNA glycosylase was not increased, although this enzyme acts on a major secondary alkylation product¹³.

The inducible DNA glycosylase activities for m³A, m³G and m⁷G appear to be associated with a single enzyme as the relative levels of induction of the three activities were the same (10-to 40-fold) in different experiments, although the small amounts of m³G and m⁷G DNA glycosylase activity in unadapted cells made accurate measurements difficult. (Neither activity was as efficiently induced as the methyltransferase for m⁶G [ref. 14].) Furthermore, we have been unable to separate the inducible DNA glycosylase activities by a variety of chromatographic procedures (DEAE-cellulose, Sephadex gel chromatography, DNA-cellulose).

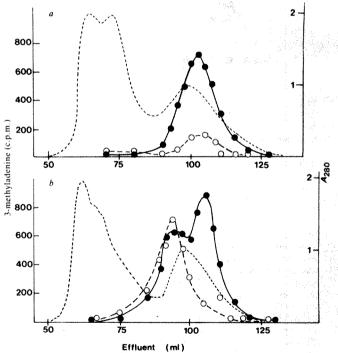

Fig. 1 3-Methyladenine DNA glycosylases I and II in E. coli B/r before and after exposure to MNNG. Cells were adapted by growth in MNNG (1 µg ml⁻¹) for 60 min. Extracts from 3 g cells were prepared by grinding with sand and partially purified by streptomycin and ammonium sulphate fractionation9. Partially purified extracts were chromatographed on Sephadex G-75 (1 cm diameter × 100 cm) in 0.3 M NaCl. 0.05 M Tris-HCl pH 8.0, 1 mM EDTA, 1 mM 2-mercaptoethanol, 5% glycerol. Duplicate 10-µl aliquots of each fraction were assayed in 100 µl standard assay mixture containing H-dimethylsulphate-treated DNA (5,000 c.p.m.), with or without product inhibition of m³A DNA glycosylase I by free m³A (3mM). a, Unadapted cells; b, adapted cells. A_{280} ; \bullet , assay without free m³A; \circ , assay in the presence of 3 mM m³A.

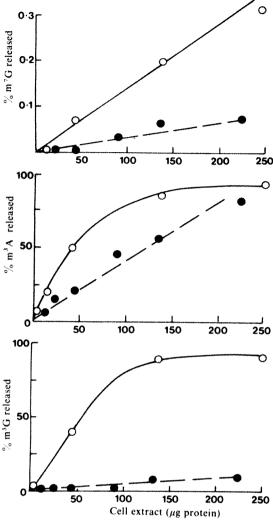

Fig. 2 DNA glycosylase activities for methylated purines in extracts of unadapted and adapted E. coli. Cultures (10 ml) of E. coli B/r were adapted by growth in MNNG (1 μ g ml⁻¹) for 60 min. Cells were collected by centrifugation, washed and disrupted by sonication in 0.07 M Tris-HCl pH 8.0, 1 mM EDTA, 1 mM dithiothreitol, 5% glycerol. Debris were removed by centrifugation (10,000 g, 5 min) and the crude extract used to assay the release of methylated purines. The assay mixture (100 µl) contained: 0.07 M HEPES-KOH pH 7.8, 1 mM EDTA, 1 mM dithiothreitol, 5% glycerol, 2 μ g ³H-dimethylsulphate-treated M. luteus DNA (50,000 c.p.m.) and 0-250 µg extract protein. After 20 min at 37 °C, mixtures were cooled to 0 °C, precipitated with 2 volumes of ethanol and centrifuged (10 min, 10,000 g). Supernatants were concentrated by evaporation to ~30 µl, supplemented with authentic methylated purines and analysed by HPLC using a Varian model 5000 chromatograph. Separation was on a Whatman Partisil 10/25 SCX column using a gradient of ammonium formate, pH 4.0, in 8% methanol essentially as described in ref. 21. The identities of released methylpurines were confirmed by paper chromatography on Whatman 3MM paper. Chromatograms were developed in methanol/ethanol/HCl/H2O (50:25:6:19) for 24 h. Radioactivity associated with the positions of authentic marker compounds was determined as described previously8. •, Unadapted cells; O, adapted cells.

Support for this conclusion comes independently from Thomas et al. 10, who partly purified enzyme II from unadapted E. coli. They found that the three DNA glycosylase activities were associated with a protein of molecular weight 27,000, and the m³A- and m⁷G-releasing activities were also shown to exhibit identical rates of heat inactivation, and to co-migrate on isoelectric focusing. The m⁷G DNA glycosylase associated with enzyme II probably accounts for the low level of this activity previously reported in E. coli¹³

Table 2 Excision of methylated purines from the DNA of dimethylsulphate-treated E. coli

Incubation time after alkylation (min)		Alkylated bases remaining in DNA (pmol per 10 ¹¹ cells)						
		m^7G	m^3A^*	m^3G	m^7A	m^1A		
Unadapted	$\begin{cases} 0\\30 \end{cases}$	124.7 106.7	0.93 0.92	1.61 0.78	4.15 2.55	0.34 0.18		
Adapted	$\begin{cases} 0\\30 \end{cases}$	114.5 109.1	0.94 0.54	0.68 <0.03	3.20 2.10	0.38 0.11		

Cultures of E. coli B/r (11) in M9 medium containing glucose (0.4%) and casaminoacids (0.1%) were adapted as described in Table 1 legend. Unadapted cultures, grown in parallel, did not receive MNNG. Adapted and unadapted cells were collected by centrifugation, washed and resuspended in unsupplemented M9 (prewarmed to 37 °C) at a concentration of 4×10^{10} cells per ml. To both suspensions was added ³H-dimethylsulphate (670 c.p.m. pmol⁻¹) to give a final concentration of 0.17 mM. After 10 min incubation at 37 °C, one-half of each suspension was diluted with 5 volumes of crushed ice and the cells collected by centrifugation. The remaining cells were diluted into full growth medium and incubated for a further 30 min before collection. DNA was extracted from cells as described in ref. 8, hydrolysed and alkylated purines analysed by HPLC as described in Fig. 2 legend.

More than 95% of the m³A initially formed was removed during the treatment with the alkylating agent8 and was not detected in the 0 min

samples.

As the potentially lethal lesion m³A is rapidly removed by the constitutively expressed enzyme I, it is unclear why an additional, inducible activity should be necessary. Further, the major alkylation lesion m⁷G appears to be an innocuous form of damage, which usually persists for a long time in both unadapted and adapted cells, although the latter have slightly better capacity to remove this base (Fig. 2). Like m³A, the minor DNA methylation product, m³G (ref. 16), projects its methyl group into the narrow groove of the DNA double helix which, unlike the wide groove, is normally free of methyl groups. In contrast to m³A, however, it is not efficiently removed in unadapted cells¹⁷. We have investigated the effect of adaptation on the rate of removal of this alkylation product in vivo. As shown in Table 2, m³G was removed quite slowly in unadapted cells, with 50% remaining in DNA 30 min after treatment. In adapted cells, however, about one-half was removed immediately during the brief treatment with an alkylating agent, and by 30 min no residual m³G was detectable. m³A was excised with a similar high efficiency in unadapted and adapted cells, whereas most of the m⁷G remained in the DNA in both cases. The minor alkylation products 7-methyladenine and 1-methyladenine, which were also resolved during HPLC of DNA hydrolysates, were inefficiently removed in adapted as well as unadapted cells (Table 2).

m³G only accounts for about 1% of the total DNA lesions after treatment of cells with methylating agents, and is thus produced at a 15-fold lower level than m³A. Since the latter, potentially lethal, lesion is rapidly removed by a constitutively expressed repair enzyme, similar amounts of m³A and m³G remain in DNA shortly after exposure. These lesions, both of which presumably can block the narrow groove of the double helix, would be expected to be of similar lethality. Consequently, the ability to repair m³G in DNA would seem to be of great advantage for cells exposed to alkylating agents. As shown here, E. coli has a low level of such a repair activity, which can be augmented following exposure to alkylating agents. A m³G DNA glycosylase activity has previously been observed in crude cell extracts of (unadapted) Micrococcus luteus 18 and human lymphoblasts 19. As m3G is removed from DNA less efficiently than m³A not only in unadapted E. coli but also in mammalian cells^{20,21}, it seems likely that m³G will generally be responsible for a major part of the cytotoxic effect of methylating agents.

We thank S. Stevens for valuable technical assistance at the MRC Cell Mutation Unit, University of Sussex, where part of this work was carried out, also Drs E. Seeberg and B. Sedgwick for bacterial strains, and Dr D. A. Goldthwait for a preprint of his paper. This work was supported in part by the Swedish MRC.

Adaptation to alkylation resistance involves the induction of a DNA glycosylase

Grethe Evensen* & Erling Seeberg†

- * Institute of General Genetics, University of Oslo, Blindern, Oslo 3, Norway
- † Division for Toxicology, Norwegian Defence Research Establishment, N-2007 Kjeller, Norway

Cells exposed to low doses of N-methyl-N'-nitro-N-nitrosoguanidine (MNNG) or methyl methanesulphonate (MMS) acquire resistance to both the mutagenic and lethal effects of a challenging dose of the same agents (ref. 1, and ref. 2 for a review). This response, termed adaptation, has been ascribed to the induced synthesis and accumulation of *O*-6-methyl-guanine (m⁶G) DNA methyltransferase^{3,4} which rapidly demethylates the m⁶G residues induced by the challenging dose³⁻⁵. Mutant studies, however, indicate that mutagenic adaptation and killing adaptation are at least partly under different genetic control and may therefore involve the induction of different repair enzymes^{6,7}. Whereas mutagenic adaptation correlates with the induction of the transferase, the data presented here show that killing adaptation can be ascribed to the induction of a DNA glycosylase. This inducible glycosylase releases the alkylation product 3-methyladenine (m³A) from DNA in vitro as does the constitutive m³A DNA glycosylase previously characterized by Riazuddin and Lindahl⁸. However, the enzymes are encoded by different genes and appear to have different roles in DNA repair in vivo.

We have previously isolated from MNNG-mutagenized clones of Escherichia coli a mutant that is extremely sensitive to MMS, unable to reactivate alkylated phages and deficient in m³A DNA glycosylase activity⁹. Further characterization of this strain (BK2106) has revealed that it carries two mutations, tag and ada, and not only lacks the glycosylase, but also is deficient in the induction of m⁶G DNA methyltransferase. Elimination of the ada mutation in this strain by P1 transduction renders the cell wild-type resistant to the lethal effects of MMS in agar medium (Table 1). However, the ada+ tag transductant (BK2114) is still unable to reactivate alkylated phages (Fig. 1) and shows considerable sensitivity to MMS exposure in buffer (Fig. 2). These observations suggested that E. coli may have

two pathways for the repair of m³A residues in DNA, one that is constitutively expressed and controlled by tag, and another that is inducible and controlled by ada. The inducible repair pathway would be turned on when the cells were exposed to alkylating agents in complete medium, but not when the cells were infected with alkylated phages. Table 1 shows that the adaptive treatment used to induce m⁶G DNA methyltransferase also induces high levels of m³A DNA glycosylase activity in the tag mutant (BK2114). Such induction is not observed in the tag ada double mutant (BK2106). Adapted BK2114 has also regained essentially normal ability to reactivate alkylated phages which implies that the inducible enzyme can replace the constitutive enzyme also in repair of phage DNA (Fig. 1). These results show that adaptation induces two different enzymes for repair of alkylated DNA, m⁶G DNA methyltransferase and m³A DNA glycosylase, and that both enzymes are under ada

Whereas constitutive m³A DNA glycosylase (TagI) in wildtype cells is inhibited by m³A (ref. 8), the inducible glycosylase (TagII) in BK2114 is unaffected by m³A (Table 1). Adaptation of wild-type cells also results in the induction of m³A DNA glycosylase activity not inhibited by m³A, indicating that the inducible enzyme in BK2114 is not a mutated form of the normal tag gene product, but is indeed a separate enzyme. Karran et al.9 previously observed a minor m3A-noninhibited m³A DNA glycosylase in both wild-type cells and strain BK2106. This enzyme is more heat-stable than TagI and constitutes ~5% of the total m³A DNA glycosylase activity in wild-type cells. It is probably the same as that which is induced to high levels in BK2114 by the adaptive treatment. In fact, Lindahl and co-workers¹⁰ have recently observed that the heatstable activity of m3A DNA glycosylase increases several-fold

in wild-type cells during adaptation.

The observation that the ada mutation prevents induction of two different repair enzymes suggests that the ada gene is a control gene for the adaptive response and that structural genes for one or both of the enzymes may be found elsewhere on the chromosome. While searching for structural gene mutants we observed that the alk-1 mutant^{11,12} was deficient in the induction of TagII, but proficient in induction of the transferase (Table 1). Similar results were obtained with another alk mutant (isolated by B. Duncan). No other enzyme defect has been linked to mutations in the alk gene. alk mutants are very sensitive to MMS exposure and it seems likely that the MMS sensitivity is caused by TagII deficiency, in which case the low levels of TagII activity present in wild-type cells must be essential for some repair not effected by TagI. It is possible

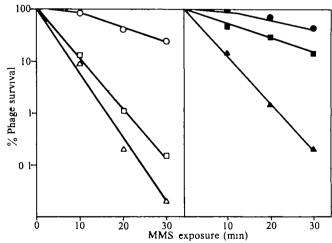

Fig. 1 Host cell reactivation of alkylated phages in non-treated and adapted cells. Phage & cI857 were exposed to 0.05 M MMS for the times indicated and plated on exponentially growing untreated (open symbols) or adapted (closed symbols) cells of AB1157 (wild type, circles), BK2106 (tag ada, triangles) or BK2114 (tag, squares). Cells were adapted as described in Table 1 legend and conditions for the plating procedure were as published previously

BD793	$\Delta alk(mgl-attP2H)$	0.16	27.0	26.2	0.5	2.9

Strain BK2106 is a MNNG-mutagenized derivative of AB1157 (ref. 9) and carries two mutations which both contribute to its MMS sensitivity. The mutation which maps at 47 min and co-transduces with gyrA is shown here to be in the ada gene and not in the tag gene as was previously assumed. Other ada mutations have also recently been mapped to the same position on the map¹³. The tag mutation responsible for m³A DNA glycosylase (Tagl) deficiency in BK2106 has now been mapped to a region between 70 and 74 min on the chromosome (G.E. and E.S., in preparation). Strains BK2106 and BK2114 (BK2106 gyrA ada⁺); BK2110 (AB1157 gyrA ada) and AB1157; and MS23 and AB1157 (refs 10, 11) are all isogeneic pairs constructed by P1 transduction. BD793 was isolated by B. Duncan and is a his⁻ eductant of phage P2-lysogenized W1485F⁻. Cell extracts were prepared by a combination of plasmolysis and lysozyme digestion as previously described¹⁴. m³A DNA glycosylase activity was assayed by the method of Riazuddin and Lindahl⁸. The numbers presented are calculated on the basis of ethanol-soluble radioactivity released from ³H-dimethylsulphate-treated DNA using various amounts of extracts ranging from 0 to 20 µg protein. In this range a linear response was obtained between glycosylase activity and extract added. Parallel assays were also run where the reaction mixtures were subjected to polyetheneimmine TLC together with authentic 7-methylguanine and 3-methyladenine. In all cases where also run where the reaction mixtures were subjected to polyetheneimmine TLC together with radioactivity released was identified as m³A. m⁶G DNA methyltransferase activity was assayed by the method of Karran et al.³ and 20 µg protein were added to each assay. Cells were induced by growth in M9 salts supplemented with 1% glucose and 1% casaminoacids in the presence of 0.5 µg MNNG for 90 min.

* Stationary phase cells calculated relative to plating on nutrient agar without MMS.

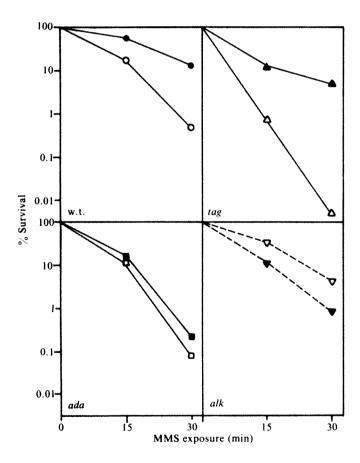

Fig. 2 Killing adaptation to alkylation resistance in wild-type and TagII-deficient mutants. Fresh overnight cultures were diluted 10-fold in K medium (M9 salts+1% glucose and 1% casaminoacids). To one-half of each culture was added MNNG at a final concentration of $0.5 \mu g \, ml^{-1}$ while the other half served as an untreated control. The cells were grown for 90 min at 37 °C and then washed once by centrifugation and resuspended in 1/10 volume of phosphate buffer. MMS was added at a final concentration $0.06 \, M$ for strains AB1157 (wild type; \bigcirc , \bigcirc), BK2114 (tag; \triangle , \triangle) and BK2110 (ada; \square , \square), and of $0.02 \, M$ for MS23 (alk-1; ∇ , \blacksquare). At intervals, samples were plated for survival after appropriate dilution. Closed symbols refer to adapted cell cultures (MNNG-treated) while open symbols represent untreated controls.

that TagII has a broader substrate specificity than TagI and is responsible for repair of a quantitatively minor but biologically important alkylation product other than m^3A . TagI has a narrow substrate specificity and a very low K_m value for its substrate, suggesting that it will quickly bind and remove m^3A from alkylated DNA. Other minor products, however, could perhaps be removed by TagII. The alk mutants seem to have less residual TagII activity than the ada mutant, which would explain the greater sensitivity of the former compared with the latter (Table 1).

Mutants defective in the adaptive response were first described by Jeggo⁷. They were selected on the basis of their deficiency in mutagenic adaptation but most of them also appeared to be defective in killing adaptation. One mutant, however, was only defective in mutagenic adaptation. Jeggo et al.6 have further reported that polA mutants defective in DNA polymerase I are defective in killing adaptation, but show normal mutagenic adaptation. These studies are consistent with the view that mutagenic adaptation and killing adaptation are due to the induction of separate repair pathways. They support the view that m⁶G DNA methyltransferase is responsible for mutagenic adaptation since transferase repair of m⁶G will not require DNA polymerase I. The ada+-dependent inducible glycosylase may well be responsible for killing adaptation because DNA polymerase I is needed to complete repair of the apurinic site formed by the glycosylase action. A critical test for this interpretation is that alk as well as ada mutants should be defective in killing adaptation. Figure 2 shows that this is indeed the case and, furthermore, that the alk-1 mutant is even sensitized by the adaptive treatment. These results therefore strongly support the view that TagII, not the transferase, is responsible for killing adaptation to alkylation resistance.

Thus E. coli seems to have two distinct m³A DNA glycosylase activities: one that is constitutively expressed and controlled by tag, and a second that is inducible and controlled by ada and alk. The constitutive enzyme appears responsible for rapid repair of m³A alkylation products in unadapted cells. The inducible enzyme seems to be required for killing adaptation to alkylation resistance and probably also for repair of some potentially lethal lesions not recognized by the constitutive enzyme in unadapted cells.

We thank Tomas Lindahl for communicating that strain BK2106 is defective in m⁶G DNA methyltransferase and for the gift of transferase substrate, Bruce Duncan and Mutsuo Sekiguchi for the gift of bacterial strains, Neil Clarke for valuable discussions, and Peter Strike for a critical reading of the

Binding of ATP to tubulin

James R. Zabrecky & R. David Cole

Department of Biochemistry, University of California, Berkeley, California 94720, USA

Microtubules are present in all eukarvotic cells and participate in a variety of cellular processes1. From recent studies it has become clear that nucleotides have a central role in the assembly of tubulin into microtubules²⁻⁵. The tubulin dimer binds two moles of guanine nucleotide: one (at the E-site) which can exchange with exogenous nucleotide and one (at the N-site) which does not exchange⁶. E-site GTP is hydrolysed during the assembly process^{4,7,8}. Microtubule assembly can be induced by ATP through a contaminating nucleoside diphosphokinase activity that regenerates GTP following its hydrolysis—this is associated with tubulin polymerization^{4,9,10}. Recent reports suggest that ATP has other effects on the assembly kinetics^{11–13}, and we have shown 14,15, using tubulin preparations lacking the nucleoside diphosphokinase activity, that ATP may play a critical part in the regulation of microtubule formation by binding to tubulin at a site which is distinct from the N- and E-sites. Kinetic data suggest a model in which ATP can act at the level of nucleation to stimulate assembly 15. We now report the first direct evidence for the binding of ATP to tubulin and show that the corresponding dissociation constant is in a range of physiological significance.

In attempting to demonstrate the existence of a tubulin-ATP complex and to determine the dissociation constant, we found that equilibrium dialysis and centrifugation methods were unsuitable because they were too slow for such an unstable protein and because of the relatively weak binding of the nucleotide. We therefore chose the method of Hummel and Dreyer¹⁶ which is rapid and maintains the protein-ligand complex in equilibrium conditions. It has been used previously to determine guanine nucleotide binding to tubulin^{17,18}. In this method the protein is placed in solution with a given amount of ligand, and then applied to a gel filtration column which is equilibrated with the same concentration of ligand. As the protein emerges from the column at the excluded volume, it bears extra ligand above the equilibrium level, while at the included volume, the ligand level is depressed by the amount of ligand removed by the protein. The amount of ligand above the baseline level is equivalent to the protein-ligand complex and can be applied to the equilibrium expression, together with the concentration of free ligand, to calculate the dissociation

Tubulin was prepared by chromatography on DEAEcellulose (Whatman DE-52) as described elsewhere⁶. It has been shown to be more than 99% homogeneous electrophoretically and to have only minimal nucleoside diphosphokinase activity15. Figure 1 shows a representative profile obtained by passage of tubulin down a Sephadex G-25 column equilibrated with ³²P-ATP. As the protein eluted from the column, there was a corresponding increase in the level of nucleotide above

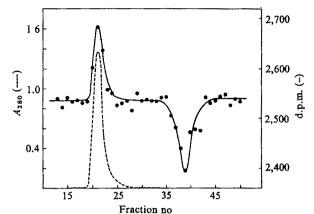

Fig. 1 Example of a Hummel-Dreyer column used to measure ligand binding. A Sephadex G-25 column (25×1 cm) was equilibrated with PM buffer (10 mM phosphate, 5 mM MgCl₂, pH 7.0) containing 20 μ M [γ - 32 P]ATP. Tubulin (\sim 10 mg ml $^{-1}$) was prepared as described elsewhere 5,10 , dialysed extensively against PM buffer, centrifuged at 140,000g for 30 min, then mixed with an equal volume of PM buffer with $40 \mu \text{M} \left[\gamma^{-32}\text{P}\right]\text{ATP}$; 0.6 ml was applied to the column followed by elution with column buffer and 0.5-ml fractions were collected. Fractions were scanned for protein at 280 nm and the radioactivity determined by spotting aliquots on glass fibre filters (Whatman GF/C) and counting these using a Beckman LS7500 liquid scintillation counter. All chromatography was performed at room temperature.

the equilibrium value followed by a trough at the included volume. We ran five such columns for a series of ligand concentrations from 10 to 100 µM. Two peak fractions from each column were used to determine the level of ligand binding. The results are presented in Table 1.

The dissociation constant was calculated based on a stoichiometry of one binding site per tubulin dimer. The relative agreement in the values of K_d obtained at various ligand concentrations supports this assumption. The stoichiometry is usually determined from the amount of ligand bound in saturating conditions. However, with such a low binding affinity, the background levels of ligand would need to be so high in order to saturate the binding site that no reasonable precision could be obtained. Moreover, as relatively weak binding results in a rather modest difference between the peak of bound ATP and a substantial baseline, even at relatively low ATP concentrations, the average value calculated for the dissociation constant, 2.3×10^{-4} M, is only approximate. Clearly, however, ATP does

Table 1 Binding of ATP to tubulin measured by the Hummel-Dreyer

Column ATP (µM)	Protein- bound ATP (µM)	Peak protein (μΜ)	mol ATP/mol protein	<i>K</i> _d (×10 ⁴)
10	1.06	12.2	0.087	1.1
	0.665	7.4	0.090	1.0
20	1.17	12.8	0.091	2.0
	0.804	8.4	0.096	1.9
25	2.02	15.9	0.13	1.7
	1.20	10.2	0.12	1.8
50	2.10	10.0	0.21	1.9
	2.25	11.1	0.20	2.0
100	2.06	15.1	0.14	6.1
	1.87	8.5	0.22	3.5

Gel filtration columns equilibrated with the indicated concentration ²P]ATP were run as described in Fig. 1 legend. The radioactivity in the two peak fractions was determined by liquid scintillation counting and the protein concentration by the method of Lowry et al.20. Kd was determined from the equilibrium expression:

 $K_d = [tubulin][ATP]/[tubulin - ATP].$

The stoichiometry was assumed to be one binding site per tubulin dimer (molecular weight 100,000).

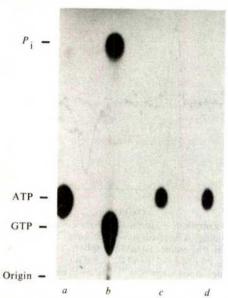

Fig. 2 Test for ATP hydrolysis following microtubule assembly. (~40 µm Tubulin (\sim 40 μ m in assembly buffer (10 mM 2-(N-morpholino)ethanesulphonic acid, 2.0 mM Mg²⁺, 1.0 mM EGTA, 3.4 M glycerol, pH 6.4) with 1.0 mM GTP and 0.2 mM [γ - 32 P]ATP was warmed to 37 °C to allow microtubule polymerization. In these conditions, ATP significantly enhances the assembly kinetics15. Monitoring of the turbidity at 350 nm indicated that a steady state was reached within 10 min. Aliquots taken at 0 and 10 min were mixed with an equal volume of 95% ethanol, cooled to 0 °C and centrifuged to remove the precipitated protein. These were spotted on to a PEI-cellulose thin-layer plate (Brinkman), then the plate was washed by immersion in 95% ethanol and dried. Ascending chromatography was performed using 1.0 M LiCl as the solvent, followed by autoradiography using Kodak X-Omat X-ray film. a, ATP standard; b, GTP and P, standard; c, assembly sample (0 min); d, assembly sample (10 min).

bind to tubulin and the calculated K_d is within an order of magnitude of cellular ATP levels, that is, ~2 mM (ref. 19). It is therefore reasonable to suggest that ATP regulates microtubule formation in vivo according to changes in its distribution and concentration.

As ATP is bound to tubulin and affects the rate of microtubule formation it is appropriate to ask whether the ATP supplies energy through hydrolysis. Therefore, microtubules were assembled in the presence of $[\gamma^{-32}P]ATP$ and the solution was analysed by TLC for the presence of free phosphate. Although microtubule formation had reached a steady state, no free phosphate was observed (Fig. 2). (The appearance of a minor amount of GTP in the autoradiogram was due to a trace of residual nucleoside diphosphokinase activity in the tubulin preparation.) To exclude the possibility that the 32P was incorporated into protein, the proteins in a similar microtubule mixture were resolved by electrophoresis and autoradiographed; no 32P incorporation was detected. As ATP is hydrolysed neither to produce inorganic phosphate (Pi) nor to phosphorylate a protein during microtubule formation, the effect of ATP on assembly must involve some other mechanism, perhaps allostery

Collective variable description of small-amplitude conformational fluctuations in a globular protein

Tosiyuki Noguti & Nobuhiro Gō

Department of Physics, Faculty of Science, Kyushu University 33, Fukuoka 812, Japan

Globular proteins in the native state undergo small-amplitude conformational fluctuations1, which can be observed experimentally, for example, as temperature factors in X-ray crystal--s or through their effects on the relaxation times in NMR6. The fluctuations can also be observed as the trajectories of each atom of a protein molecule generated by the theoretical method of molecular dynamics^{5,7,8}. These studies indicate that atoms or groups of atoms in the molecule, especially those near the surface, are in a 'fluid-like' state, which means that the forces acting on them have an impulsive character and the temperature factors obtained from X-ray crystallography have an anharmonic temperature dependence. More work is clearly needed to characterize better the state of the protein interior. Thus we have now calculated the shape of the conformational energy surface of a small protein, basic pancreatic trypsin inhibitor (BPTI), near its minimum. We find that for most degrees of freedom corresponding to collective conformational changes, the protein molecule behaves harmonically or like a solid.

In thermal equilibrium a protein molecule takes on a microscopic conformation with a probability determined by the con-

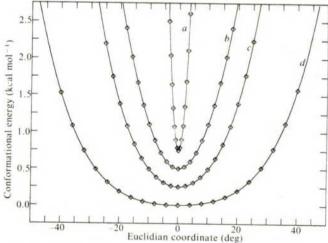

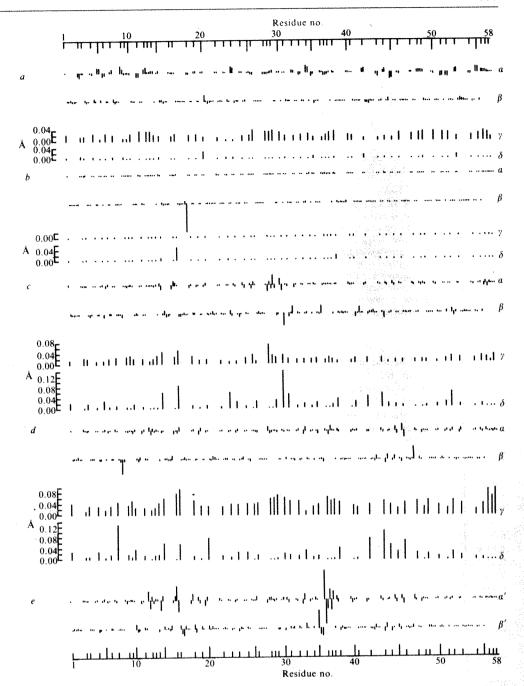

Fig. 1 Conformational energy curves calculated for actual conformational changes induced by variations in four variables, variables 37 (a), 118 (b), 179 (c) and 235 (d). The abscissa is the coordinate measured by euclidian distance defined as $d = \{\sum_{i=1}^{241} (\Delta \theta_i)^2\}^{1/2}$, where θ_i is a common notation denoting either ϕ or ψ or χ , and $\Delta\theta_i$ is the current value of θ_i minus that of θ_i at the energy minimum. Conformational energy values for a, b and c are off-set by 0.75, 0.50 and 0.25 kcal mol⁻¹ respectively for c are off-set by 0.75, 0.50 and 0.25 kcal mol respectively for clarity. \diamondsuit , Calculated conformational energy. —, Best-fit curves of the form of $B\xi^2 + C\xi^3 + D\xi^4$. Best-fit values of $B(\text{kcal-mol}^{-1} \text{deg}^{-2})$, $C(\text{kcal mol}^{-1} \text{deg}^{-3})$ and $D(\text{kcal mol}^{-1} \text{deg}^{-4})$ for the four curves are: a, 0.15, 0.1×10⁻², 0.1×10⁻³; b, 0.0061, 0.3×10⁻⁷, -0.6×10⁻⁶; c, 0.0023, 0.2×10⁻⁵, 0.1×10⁻⁵; and d, 0.00032, 0.3×10⁻⁶, 0.4×10⁻⁶. The first three curves are essentially parabolas in the range of thermal fluctuations. A pharmonic tially parabolas in the range of thermal fluctuations. Anharmonicity is observed in the last curve.

Fig. 2 Make-up of four eigenvectors of the second-derivative matrix, numbers 37 (a), 118 (b), 179 (c) and 235 (d), and equilibrium correlations of fluctuations in dihedral angles (e). In a-d, the value of the jth component, uin of the ith eigenvector is represented by a bar (upwards when positive, downwards when negative) against serial number j of variable dihedral angles. When j refers to a main-chain angle, the bar is shown in lines α ; when to side-chain angle, in lines β . Dihedral angles in the kth residue are arranged in the order ϕ_k , χ_k^1 , numbers, Residue $\chi_k^{\ell}, \ldots, \psi_k$. instead of the serial numbers of dihedral angles, are given on the abscissa. The displacements of atoms in collective conformational changes caused by changes in the collective variables are shown in lines y and δ : γ , displacements of C^{α} atoms, and δ , average displacements of sidechain atoms relative to a local framework fixed to main-chain atoms in the same residue. The magnitude of the collective conformational change is taken as the root mean square thermal deviation of collective variable ξ_i calculated from the actual energy curve shown in Fig. 1. e, Example of relative equilibrium correlations of fluctuations in dihedral angles defined by $\langle \Delta \theta_i \Delta \psi_{35} \rangle / \langle (\Delta \theta_i)^2 \rangle^{1/2} \langle (\Delta \psi_{35})^2 \rangle^{1/2} \rangle$. α' and β' refer to main-chain and side-chain dihedral angles. Residue 35 is located in an extended strand, which is roughly sandwiched between two other strands; it touches residue 11 in one strand and residue 17 in the other.

formational energy according to the Boltzmann law. The distribution of various fluctuating conformations can therefore be clarified by elucidating the shape of the conformational energy surface near the minimum point corresponding to the most stable conformation. Very near to the minimum, the energy surface is a multidimensional parabola characterized by the second-derivative matrix at the minimum.

The multidimensional parabola is most easily described in terms of a set of collective variables, $\{\xi_i\}$, corresponding to the eigenvectors of the second-derivative matrix

$$\xi_i = \sum_i u_{ij} \Delta \theta_i \tag{1}$$

where u_{ij} is the jth component of the ith eigenvector and $\Delta\theta_i$ is the deviation of the jth internal variable from that at the minimum point. A change in the variable ξ_i causes simultaneous and correlated displacements of many atoms in the molecule. Thus $\{\xi_i\}$ s are predicted to be natural variables describing conformational fluctuations in which strong correlations are known to exist among atomic displacements.

In terms of the collective variables, the conformational

energy, E, near the minimum point is given by

$$E = \frac{1}{2} \sum \lambda_i \xi_i^2 \tag{2}$$

where λ_i is the *i*th eigenvalue of the second-derivative matrix. For the range in which equation (2) applies, the collective conformational changes caused by changes in each ξ_i are mutually independent (that is, not correlated), and any conformational change can be predicted as superpositions of changes in ξ_i .

If the conformational energy can be expressed by equation (2), the conformational fluctuations will be harmonic or solid-like. Our previous study using a Monte Carlo method suggested that for many collective variables, the conformational energy was parabolic in the range of thermal fluctuations. Now we have calculated the second-derivative matrix at the minimum energy. Energy curves are calculated for a thermal excitation range of 0.3 kcal mol⁻¹ for actual conformational deformations caused by changes in each of the collective variables.

As in our earlier work⁹, bond lengths and bond angles in the protein are fixed and only dihedral angles of a main chain $\{\phi, \psi\}$ and side chains $\{\chi\}$ are treated as variables. The conformational

Table 1 Classification of anharmonic energy curves

		No. of anharmonic collective variables Type

Total		7	24	8	2	2	43

The energy curves for all the collective conformational changes are well fitted by fourth-order curves of the form $B\xi^2 + C\xi^3 + D\xi^4$, except for four curves classified as types IV and V. A curve is harmonic when the terms $C\xi^3$ and $D\xi^4$ are insignificant in the range of thermal fluctuations. As a measure of the range of thermal fluctuations, we take $[-\xi_0, \xi_0]$, where ξ_0 is defined by $\frac{1}{2}B\xi_0^2 = 0.3$ kcal mol⁻¹. A curve is anharmonic if $|C\xi_0^4/B\xi_0^2| \ge 0.1$ and/or $(D\xi_0^4/B\xi_0^2) \ge 0.1$, and may be one of five types according to its shape. Type I: curves where $|C\xi_0^3/B\xi_0^2| \ge 0.1$ and $(D\xi_0^4/B\xi_0^2) \ge 0.1$. In conformational changes caused by variations in these collective variables, large changes in dihedral angles and atom positions are confined to one or two side chains. If curves where $1.0 > (D\xi_0^4/B\xi_0^2) \ge 0.1$. III: curves where $(D\xi_0^4/B\xi_0^2) \ge 1.0$. Conformational changes caused by variations in collective variables of types II and III are not localized in any part of the molecule. 4 of 24 type II curves and 5 of 8 entries in type III curves have non-negligible third-order terms, that is, $|C\xi_0^3/B\xi_0^2| \ge 0.1$. IV: conformational changes are localized in one or two side chains with smaller changes elsewhere. A peak of the energy curve is due to torsional energy for dihedral angle(s) of the side chain(s). V: Almost free rotation of a side chain (lysine) dihedral angle. Peaks are due to the non-bonded energy.

space therefore consists of 241 variables (116 main-chain and 125 side-chain dihedral angles). Hydrogen atoms are not treated individually but are included in calculations for the atom to which they are bonded, except for those expected to participate in hydrogen bonding. Geometrical parameters and energy functions are those used previously9, except for the energy functions for hydrogen bonding; energy functions of the form of (Ar⁻¹²+Br⁻¹⁰) are used. Solvation effects are not considered, that is, the molecule is treated as being in vacuo.

By starting from the conformation with the least energy in the previous Monte Carlo study, the conformational energy can be minimized in the 241-dimensional conformational space by the Newton method¹⁰ using first and second derivatives. The minimization is continued until a conformation is found in which all components of the first derivative are <0.02 kcal mol⁻¹ deg⁻ and all eigenvalues of the second-derivative matrix are positive.

Figure 1 shows representative energy curves calculated for actual collective conformational changes. Serial numbers are given to the collective variables, corresponding to collective conformational changes in the descending order of the magnitude of the eigenvalues. For 198 of 241 collective conformational changes, the energy curves agree well with the parabola derived from the second-derivative matrix by the criterion described in Table 1 legend.

Deviations from the parabolas are observed in curves for the remaining 43 collective variables. All but five of them are members of the 61 softest variables (variables 181-241; see Table 1). We classified the 43 anharmonic collective variables into five types; 31 are such that the fourth-order terms have non-negligible positive contributions in the thermal fluctuations (see, for example, curve d in Fig. 1).

Thus, for many (~80%) of the collective conformational changes the conformational energy is harmonic. This strongly supports the use of collective variables to describe conformational fluctuations.

The nature of the conformational change induced by variation in the collective variable, ξ_o is defined by the components, u_{ip} of the eigenvector. The make-up of typical eigenvectors is shown in Fig. 2. Due to the complexity of the protein structure, there are many types of collective variable, most of which express non-local conformational changes (Fig. 2a, d). Whereas in variable 118, changes in dihedral angles and atom positions are localized mainly in one surface side chain (Fig. 2b), in variable 179, changes are localized mainly in a flexible loop structure consisting of residues 26-30 (Fig. 2c).

To characterize the shape of the multidimensional energy surface in the range of thermal fluctuations, contributions from higher-order cross-terms must be known. Even among the

harmonic variables these may be non-negligible. Some may cause anharmonic fluctuations such as transitions between energy minima. The anharmonicity observed in a few variables and higher-order cross-terms not considered here may account for the anharmonic behaviour of the conformational fluctuations observed in X-ray temperature factors²⁻⁵ and molecular dynamics5,7,8

There are two difficulties in our approach. First, the constraints on bond angles increased the energy barrier separating energy minima8. If the bond angles were to relax adiabatically, the conformational energy surface might be softer than we have allowed here, in which case the number of harmonic collective variables might be an over-estimate. Second, by neglecting the effects of solvent molecules, some changes in the surface of the molecule may not have been considered. However, our qualitative conclusion, that conformational fluctuations are largely harmonic and can therefore be described in terms of the collective variables, still holds. Because kinetic energy has not been considered, the collective variables defined here do not correspond to normal modes of vibration. The collective variables are useful in describing populations of conformations in equilibrium.

If we assume that, in the thermal range considered, the energy surface can be approximated in all degrees of freedom by a multidimensional parabola, we can calculate equilibrium correlations of fluctuations in dihedral angles from the secondderivative matrix (see Fig. 2e). Strong correlations exist between dihedral angles that are close in space, reflecting various collective conformational changes in the protein. If we can assume harmonicity of the energy surface, we will be able to calculate various quantities that reflect conformational fluctuations from the second-derivative matrix and to compare them with experimental results.

We thank Professor T. Ooi and Dr K. Nishikawa for providing a computer program to calculate conformational energy. Computation was done at the computer centres of Kyushu University and the Institute for Molecular Science. This work was supported by grants-in-aid from the Ministry of Education, Japan.

MATTERS ARISING

Pleistocene and Holocene climates in Africa

In examining the question of Pleistocene and Holocene climatic fluctuations in North-West Africa, Sarnthein et al. distinguish between hypotheses that suggest distinct latitudinal shifts and those assuming stable latitudinal positions but contraction and expansion of the arid zone, and they cite Nicholson and Flohn² as an example of the former. This is clearly incorrect. We do indicate such shift at 18,000 yr BP, but not for later periods: and we clearly show a pronounced contraction of the arid zone during the climatic optimum at 6,000 yr BP. We do suggest that both a shift in the position and changes in intensity of the major circulation features are responsible for African rainfall changes in the late Pleistocene and Holocene.

Sarnthein et al. cite primarily two lines of evidence of 'stable' latitudinal positions of circulation features. The first, concerning the location of the westerly wind belt over North-West Africa, is contradicted by recent findings3, which suggest it extended to 20-40° N at 18,000 yr BP and at present. Furthermore, the main Pleistocene displacement of that zone would probably have been during the summer and its southern most position (winter months) may not have differed much from present. The second piece of evidence is the mean position of the 'Harmattan' dust outbreaks, which are related to the midtroposphere jet. The term 'Harmattan' is misused: today it is generally understood to be the surface, northeasterly tradewind flow and not the upper-level easterlies. Furthermore, one cannot conclude, as those authors did, that the position of the ITCZ (intertropical convergence zone) is necessarily coincident with the position of the dust carried by the 'Harmattan' flow (or jet). This flow is a direct consequence of the temperature gradient between the Sahara and the relatively cooler and more humid air further south4. As long as the southern Sahara exists, and given the fixed Atlantic boundary to the south, the position of this easterly flow aloft (the mid-tropospheric jet) is relatively fixed. The ITCZ, on the other hand, is both dynamically and thermally determined and its position most directly inter-hemispheric thermal reflects differences, which did vary greatly throughout the late Pleistocene and Holocene. Although at present the ITCZ and related disturbances over West Africa coincide with the mid-tropospheric jet and Harmattan, they need not necessarily

The shear associated with the jet is critical for the formation of West African

disturbances4 and a weakened easterly flow could conceivably, as suggested by Sarnthein et al.1, have been a factor in sub-Saharan aridity ~18,000 vr BP. Indeed, this may also have been a factor in the recent Sahel drought5. However, the authors present no evidence of a stable position of other circulation features, such as the westerlies or the ITCZ, and it is highly unlikely that the latter was not displaced towards the equator in late Pleistocene, when glaciation and temperature changes were most pronounced in the Northern Hemisphere and interhemispheric thermal contrast must have been minimal.

TETZLAFF, SARNTHEIN AND WOLTER REPLY—The comments of Nicholson give us the opportunity to clarify possible misunderstandings of our concepts and conclusions on the underlying causes of climatic change in North Africa¹. Nicholson particularly questions our evidence of 'stable' latitudinal positions of circulation features.

With regard to the extension of the westerlies, we basically agree with Nicholson, although we did not say too much about it in our article¹ and cited only indirect evidence. The westerlies indeed extended to 20–40° N over North-West Africa, in both periods considered, not only at 18,000 yr BP, but also at the present time. Nevertheless, average westerly wind vectors are substantiated on land only by proxy data² for precipitation due to synoptic disturbances in the westerlies.

In the Atlantic, the subtropical gyre and the coastal upwelling off the western Sahara essentially did not have a more southerly position around 18,000 BP and this provides additional evidence for a stable southern fringe of the westerlies during both winter and summer average seasons³. This contradicts a general equatorward displacement of the climatic belts south of the present westerlies in the Northern Hemisphere during cold stages, as suggested by Nicholson.

The other feature questioned—the relationship between the mean position of dust outbreaks and the position of the middle and lower tropospheric part of the ITCZ, in particular the monsoonal front-needs a deeper discussion of the meterological structures. Along a trajectory in the continental trades southwards, the average temperature of the lower would continuously troposphere increase^{4.5}, at ~18,000 BP as well as at present. The middle tropospheric easterly winds which carry the main Saharan dust outbreaks require the opposite horizontal gradient. This means a southward sloping isobaric plane on the southern fringe of the subtropics. Like other authors⁶, we call these easterlies 'Harmattan' for our convenience.

We again agree with Nicholson that an equatorward temperature such decrease can be produced only by the cooler tropical air masses, the northern boundary of which is called monsoonal front and coincides with the ITCZ near the surface over land at the present. Finally, the maximum slope of the isobaric surface can also result in barotropic instability providing the energy for the easterly waves. This implies that the easterly (Harmattan) winds, the lower tropospheric parts of the ITCZ (Fig. 1a in ref. 1) and the easterly waves (including the dust transport in their wake) are three different effects of the same dynamic structure and their positions are necessarily closely related. We feel that some authors5 imply a connection between the positions of the maximum rainfall zone and the northern boundary of the monsoonal air masses. They are assumed to be coupled by the downdrafts of the storms in the rainfall zone. However, recent findings5 do not confirm such a direct relationship. Of course, the historical position of the ITCZ in North Africa is averaged over a number of cyclic processes on the synoptic, annual and long-term climatic scale, but it is not necessarily coupled with interhemispheric temperature differences as postulated by Nicholson. A separate dynamic ITC (intertropical convergence) equatorwards of the monsoonal front over Africa at 18,000 yr BP is theoretically possible, but not probable. As a result we consider our conclusions1 valid. They strongly suggest that the dust-carrying winds, the Harmattan and the Trades, the subtropical anticyclone and also the ITCZ near the surface were not displaced equatorwards in western North Africa during the last glacial stage. Thus the fluctuations in the degree of sub-Saharan aridity/humidity should be related to factors such as the intensity and frequency of rain-bearing disturbances8 rather than to the average surface position of the ITCZ.

coincide.

In our article¹, we did not intend to misinterpret Nicholson and Flohn⁹ when citing their hypothesis of distinct latitudinal shifts of the subtropical climatic belt from interglacial to glacial times. Accidental over-simplification of the alternatives may be one of the reasons for the apparent wrong citation. On the other hand, we feel rather corroborated in our statement by the comments of Nicholson discussed above.

Western diets and faecal nitrosamines

THE paper by Suzuki and Mitsuoka¹, while apparently demonstrating clear differences in nitrosamine production in individuals on different diets, makes unwarranted claims for the significance of these findings.

Japan has a low incidence rate of large bowel cancer compared with the United States² or Australia³. International correlation studies^{4,5}, studies of subcultures within societies⁶, and case-control and cohort studies of individuals⁷⁻¹⁰ have implicated dietary factors in colon carcinogenesis. Current hypotheses involve fat^{4,9,11}, fibre^{9,11}, alcohol¹¹, female sex hormones¹², vitamin A¹³, and cruciferous vegetables⁸ either as promoting colon cancer, via endogenous and bacterial bile acid metabolism, or as protective agents.

To test the hypothesis that a balanced Western diet constitutes a greater risk of exposure to nitrosamines (which act as initiating agents in some cancers) it is necessary to design an experiment which actually uses a balanced Western diet. The

diet used by Suzuki and Mitsuoka bears no resemblance to a normal Western diet. Specifically, the energy content of a typical Western diet^{14,15} is 9.7-10.5 mJ per is 9.7-10.5 mJ per day, compared with 11.8 mJ per day in the study of Suzuki and Mitsuoka. As a percentage of energy, protein intake is normally 12-15% (as opposed to 25%), fat ~40% (compared with 55%), carbohydrate ~45% (as opposed to 20%). In some European countries, certain vegetables may be consumed for breakfast but nowhere are salad vegetables eaten for breakfast. Indeed these vegetables were deliberately added to the 'typical' Western breakfast to increase nitrate intake. This ensures a good test of an hypothesis but not the one we are led to believe is being tested by the authors.

Although Suzuki and Mitsuoka have established that a very high protein and fat diet with a large intake of nitrate increases the faecal output of nitrosamines, they have not demonstrated that this has anything to do with differences existing in the real world.

SUZUKI AND MITSUOKA REPLY—We agree with Potter that the diet used in our study does not exactly resemble a typical Western diet. To determine that nitrosamine formation in the intestine depends on diet, we used in our experiments a diet which contained a large

amount of nitrosamine precursors. Our study demonstrated that the faecal output of nitrosamines was increased by this kind of Western-style diet. However, we cannot implicate these diets directly in the aetiology of colon cancer. Further investigations of nitrosamine formation in the intestine in populations of high and low risk for colon cancer are necessary.

With respect to the p.p.b. analysis of nitrosamines in biological specimens, there are several problems associated with artefacts and contamination during the analysis. Nitrosamines are generally extracted from the specimens in alkaline conditions, because this inhibits nitrosation. We have noticed recently, however, that artificial formation of nitrosamines occurs in these conditions. This reaction seems to resemble the 'alkali effect' reported by Tozawa1. We have used 1 mM of morpholine to monitor nitrosamine formation during the analysis, as morpholine is nitrosated 500 times more readily than piperidine2. However, we have recently found that morpholine is more difficult to nitrosate than piperidine in alkaline conditions, which renders morpholine unsuitable for use as a monitor of possible artificial formation of nitrosamines. We are re-investigating the faecal output of nitrosamines, thus our data³ may require correction.

Matters Arising

Matters Arising is meant as a vehicle for comment and discussion about papers that appear in *Nature*. The originator of a Matters Arising contribution should initially send his manuscript to the author of the original paper and both parties should, wherever possible, agree on what is to be submitted. Neither contribution nor reply (if one is necessary) should be longer than 500 words and the briefest of replies, to the effect that a point is taken, should be considered.

BOOK REVIEWS

Public rights, private land

Timothy O'Riordan

ANN and Malcolm MacEwen are an amiably dedicated couple who have spent the past three years on an exhaustive labour of love. They have visited each of the ten national parks of England and Wales, interviewed countless officers and members and consulted many other informed people, all with the aim of finding out whether the national park idea is alive and well in the land. To this important task they have also brought their own impressive knowledge of conservation and planning matters, plus Malcolm MacEwen's experience as an appointed member to the Exmoor National Park Committee. During that time he fought a partially successful campaign to protect Exmoor's magnificent moorland from being ploughed up and reseeded by landowners ready to capitalize from the grants and guaranteed prices available for intensive livestock production.

Their report is an important analysis of the current state of national parks in England and Wales. Together with another recently published document, The Economy of Rural Communities in the National Parks of England and Wales (1982), written by the Tourism and Recreation Research Unit at the University of Edinburgh, it provides by far the most comprehensive and sobering statement of the state of health of the national parks since the publication of the Report of the National Park Policies Review Committee (the Sandford Report; HMSO, 1974).

The MacEwens set out to discover whether the national park authorities are able to preserve for the nation the magnificent conservation and scenic heritage that caused the parks to be established in the first place. They believe that it is the duty of government (both central and at the national park level) to safeguard in trust

for all citizens the many diverse scenic and natural history habitats which they claim have superior public rights to the private development rights of individual landowners. They are also very much aware that the national park landscapes are the product of care: they are not "natural" in the strict ecological sense, but a kind of semi-wild "garden" tended by generations of inhabitants to create a unique blend of cultural and

National Parks: Conservation or Cosmetics? By Ann and Malcolm MacEwen. Pp.314. Hbk ISBN 0-04-719003-5; pbk ISBN 0-04-719004-3. (George Allen and Unwin: 1982.) Hbk £15, \$35; pbk £8.50,

natural processes. The MacEwens call this characteristic "semi-wildness" and note that it has four vital elements: the opportunity for people to touch experience face to face; the repository both of natural and human history; the resource of space and openness; and a state where, until recently, man's relationship with nature has been relatively harmonious.

The MacEwens clearly regard these features as vital to the life-blood of the nation but realize that the future of the national parks cannot be separated from the future of the British countryside as a whole. Like the Edinburgh group, they are acutely aware that much of the national park land is harsh and economically inhospitable. The remote uplands are losing their working populations as agriculture is shedding labour, forestry is not attracting labour and the well-known problems of expensive and ill-provided transport lead to loss of job opportunities and services. Many of the national parks are suffering from the economic decline which is affecting remote rural Britain generally, and the local economies are so structurally weak that they cannot readily exploit the opportunities provided by tourism and the promotion of craft industries.

But the MacEwens' main criticism is levelled at the Ministry of Agriculture, Fisheries and Food (MAFF), the Common Agricultural Policy (and by implication, the Inland Revenue) for failing to recognize the social and conservation-related re-

percussions of policies favouring intensive agriculture and coniferous forestry. By means of a number of skilfully presented case studies they document how it pays landowners to exploit the public right of landscape in their own short-term private interest, aided and abetted by grants and tax incentives that positively encourage the destruction of the national park heritage. They further point out that the national park authorities are virtually powerless to stop this, lacking both the powers and the budgets to halt the decline. In addition, the MacEwens believe that the membership of national park committees should be less parochial and more committed to the original national park ideals.

But lest it be thought that the MacEwens are seeking a kind of landscape museum, one should make clear that they are anxious to extend public access to the semi-wild, and to develop the scope of environmental education and countryside interpretation so that many more people can enjoy the experiences that evidently mean so much to them. They are equally anxious to see a renaissance in rural economies favouring the retention of labour in agriculture and forestry so that key elements of the national park landscape can be retained. Indeed this is a critical point of their argument, and most relevant to any future government seeking to grapple with the problem of employment.

This means a major re-examination of MAFF policies and of the tax incentives favouring expenditures in social capital where this has both conservation and economic value. The MacEwens deplore the lost opportunity in the Wildlife and Countryside Bill debate when Lord Sandford's imaginative amendment, passed against the Government's wishes, fell in the Commons. This provision would

The price of farming? The broadleaved woodlands here in Patterdale, and elsewhere in the Lake District National Park, no longer regenerate naturally because of over-grazing.

have enabled MAFF to invest in rural enterprises to maintain employment in agriculture and related activities so as to promote conservation. The new clause is terribly weak, merely encouraging MAFF to further the cause of conservation but only within the narrow confines of their existing remit. The MacEwens are equally critical of the final shape of the Wildlife and Countryside Act with its inbuilt assumption that landowners are entitled to agricultural and forestry grants so that when such grants are denied on conservation grounds, the national park authorities will have to buy them out possibly to the tune of the profit foregone. They correctly emphasize that while these provisions are bad enough, the failure of the Act to cover the countryside outside the national parks and sites of special scientific interest could be disastrous. For here no notification is required of agricultural or forestry activity likely to be detrimental to conservation. It is hardly surprising that the agricultural community is anxious about its public image.

Like the Edinburgh group, the MacEwens conclude that the national park

authorities are toothless watchdogs, that their record has been more one of cosmetics than conservation and that the maze of bureaucratic interests with a finger in the countryside pie is emasculating coordinated action. They argue for a unification of the Nature Conservancy Council and the Countryside Commission (and possibly, eventually, the Development Commission?) on the grounds that the distinction between conservation and landscape is an unnecessary one, which may well lead to a continual weakening of the conservation cause.

There is little doubt that in the wake of the passage of the Wildlife and Country-side Act, the national park idea, already under fire because of changing economic circumstances in remote rural areas, is even more under threat. The MacEwens' arguments should be taken seriously or the nation is in danger of losing something that it will find very difficult to replace.

Timothy O'Riordan is Professor of Environmental Sciences at the University of East Anglia. He is currently preparing the rural section of the UK response to the World Conservation Strategy. ative linguists have ignored "meaning" and "understanding"? The central themes of Chomsky's work have always included the grammatical representation of thematic structure (who did what to whom with what), the referential possibilities of anaphoric elements, and the interpretation of the logical vocabulary of natural languages. There may be more to meaning than this, but surely these topics are part of "semantics" in anyone's story?

Hörmann's final point, that the study of language-use has not been advanced by recent psycholinguistic research, seems at first blush a particularly odd way of describing a period that has seen notable advances in modelling sentence parsing and production. Apparently, that area is not what Hörmann refers to as "languageuse". His fulminations are rather based upon the failure of generative linguistics and psycholinguistics "to predict events as they occur in everyday life". Hörmann's claim may be confidently conceded, although the complaint smacks of expecting Newton's laws of motion to predict when the last apple will fall from the tree in my back garden.

The bone of contention is this: common sense and Professor Hörmann know that there's a lot going on when two people talk with each other. In addition to speaking a common language (English, German, Malagassy, or whatever), the participants also bring to bear their tacit grasp of conversational maxims, and their vast knowledge of "the way the world is". Professor Hörmann notes, correctly, that theories of generative grammar do not explain everything about these "acts of meaning and understanding". But he then concludes that such theories therefore explain nothing. This hasty dismissal rather misses the point that however much extralinguistic factors may aid in understanding what someone really means, the greatest help surely comes from knowing the other person's language. It is precisely this knowledge that grammars explicate. The scope of formal grammars may, however, be very restricted. For example, Chomsky's position is that a particular level of linguistic representation - "the syntax of logical form" - is the interface between sentencegrammar and other faculties of mind implicated in the wider sense of the weasel word "semantics". Beyond the level of logical form no sharp dividing line is drawn between the "literal" meaning of a sentence and its interpretation in the light of the beliefs, knowledge and pragmatic inferences that can be brought to bear upon it. It is, of course, an empirical issue whether mental representations do indeed partition in this fashion. The pity is that Professor Hörmann obscures these topics by arguing that sentence-grammars fail to solve problems they were never intended to solve.

The prosecution of syntax

John C. Marshall

To Mean — To Understand: Problems of Psychological Semantics. By H. Hörmann. Pp.337. ISBN 3-540-10448-8. (Springer-Verlag: 1981.) DM88, \$41.95.

MUCH of Professor Hörmann's latest book is taken up with attacks upon modern (that is, Chomskyan) linguistics and the psychological experimentation that has drawn upon Chomsky's ideas. Hörmann senses that the swings and roundabouts of outrageous fashion are deserting the paradigm that has dominated the field since 1957. "It is not uncommon", he writes, "that following a period of turbulent growth, a skeptical mood builds up and doubts begin to be expressed as to the rationale of progress achieved and the extent to which the position reached coincides with the original goals".

The particular malaise that Hörmann claims to detect has three main symptoms: current linguistic models are approaching "a level of complexity at which extreme sophistication borders on folly"; these models reveal a "widening gap between linguistic theory and the realities of language"; the last 25 years of work in linguistics and psycholinguistics has "contributed very little to a clarification of the problems of language use". Hörmann's antidote, as summarized in the last paragraph of the book, is that we should study how "the hearer is driven by the intentionality of his process of living-into-theworld", how "as he passes from one level to the next, the sounds, words, and

sentences of the language become transparent" and "fade away to make room in his consciousness for the meaning meant".

I have no doubt that, sociologically, Hörmann's remarks are exactly to the point and that both his diagnosis and his remedy will strike a responsive chord in the breasts of many psychologists. Intellectually, however, the argument is more dubious. Consider first the charge of overcomplexity. No one would deny that, ceteris paribus, simple grammars should be preferred to intricate ones, but it is nature, not the linguist, that determines how elaborate the grammars of natural language are. And in any case, Hörmann seems unaware that a radical simplification of linguistic theory has taken place over the last decade; the proliferation of rules and rule-types that characterized generative syntax in the mid-1960s has been replaced by a system of very general principles whose interaction is responsible for the appearance of "phenotypic" diversity.

In order to appreciate the second complaint one must consider what "the realities of language" entail. For Hörmann,

human language is language because it is used by people for a purpose, namely, to live with other people. The purposeful use of language is embodied in acts of meaning and of understanding; in these acts the essence of language is integrated with the condition of man.

While the passage may be a trifle purple, the sentiments are surely unimpeachable. But why does Hörmann believe that gener-

John C. Marshall is in the Neuropsychology Unit, part of the Neuroscience Group at the Radcliffe Infirmary, Oxford.

Littermates and guesstimates

Barry Cox & Michael Stoddart

The Mammalian Radiations: An Analysis of Trends in Evolution, Adaptation, and Behaviour. By John F. Eisenberg. Pp.610. US ISBN 0-226-19537-6; UK ISBN 0-485-30008-7. (Chicago University Press/Athlone: 1981.) \$45, £32.

THE theme of John Eisenberg's book is the relationship between three aspects of mammals: their anatomy and physiology, the way in which they exploit their different habitats, and their behaviour and social structure. Clearly, these aspects must be integrated in any species, but Eisenberg goes further in attempting to compare the patterns of integration in different mammalian groups, and to suggest general trends that extend from one group to another.

The first 74 pages deal with the relationship between the areas of origin of the different groups and the changing continental configurations, and survey what Eisenberg calls "the early radiations" - monotremes, marsupials, edentates and lemurs. In the next 150 pages he deals with the remaining orders of mammal in similar fashion. He is at his least authoritative in the historical and taxonomic section, for he shows the Marsupialia as already in existence in the Lower Cretaceous, while the suggestion that monotremes evolved from multituberculates that reached Australia is to found one highly dubious hypothesis upon another. After uniting the South American ungulates with such African forms as elephants, Eisenberg notes that this suggests that they had a common ancestor in those areas before the two continents separated - though the separation took place in the mid-Cretaceous, long before the differentiation of the ungulate eutherians. Furthermore, are the marsupials and edentates simply part of an "early radiation" of mammals? Since Eisenberg is attempting to deduce phyletic trees of behavioural traits, and these trees are in turn founded upon the classification and history derived from morphological studies of fossil and living forms, it is essential that he is accurate in these fundamental assumptions.

Eisenberg's method and assumptions are clearly explained on p.12.

From the initial radiations, there are today some living mammals, mostly in the tropics, that in many morphological features show relatively little modification from the original stocks... it seems legitimate to infer that certain morphologically conservative species inhabiting niches in the tropics represent forms that are in a sense adapted to a 'conservative niche'. Thus a phylogenetic reconstruction of mammalian behavioural evolution should start with generalizations developed by comparing morphologically conservative forms that occupy what might be considered the niches of the Paleocene.

He goes on to comment (p.42) that "The

age of the edentate and pholidote lineages allows them to serve as a basis for comparison with the remaining radiations of the eutherians". Finally (p.49)

If the Edentata are among the most primitive living eutherians, then the behaviour of a 'conservative' dasypodid such as *Euphractus* has great significance for comparisons with other morphologically conservative mammals. Unfortunately we have virtually no field data . . . We must therefore rely heavily on captive studies.

The gaps in this chain of reasoning are obvious. To what extent is any niche today equivalent to a niche in the Palaeocene? Are armadillos really morphologically conservative? If they are, at least in those characters that condition their ecological niche, to what extent does this allow us to deduce that they are also conservative in their reproductive and behavioural strategies? How much meaning is there in the concept of a "phylogenetic reconstruction of mammalian behavioural evolution"? These are important reservations, that must be raised now because they counsel caution in reading the rest of the book.

In Chapters 17-23, Eisenberg discusses what he terms "macrophysiology and adaptation" — an integration of dietary specializations and ways of life. This is the classical stuff of mammalian adaptive radiation, and his approach is useful and thought-provoking. For example, why are fossorial niches incompletely occupied in the tropics, and why are more "macroniches" filled in North America than in Europe or North Asia?

In the final 100 pages of text, Eisenberg develops the theme that there was originally a common basic mammalian behavioural repertoire, which has been adapted through natural selection in the

various diversifying lineages. He first attempts to identify this repertoire by comparing various patterns of behaviour in terrestrial mammals; this chapter is brief and rather unsatisfactory. However, in a detailed and most valuable analysis of social organization, Eisenberg spiritedly tries to correlate such behavioural systems as mating, rearing, foraging and refuging. He then extends his net to show relationships between demographic, ecological and sociological variables in a wide range of species. The use of arbitrary numerical values for qualitative characteristics (e.g. "reproductive rate" is scored from 1 to 7) is understandable but can be misleading. Many species vary their reproductive output and adopt a slightly different social organization at different altitudes or latitudes, so the reader must beware of these oversimplifications. However, the author seems more at home in this section than in the earlier parts of the book, and his extrapolations should fuel many a coffee-room debate.

There is an excellent and wide-ranging bibliography of over 1,700 references, and Eisenberg has had the happy idea of entering many of these in group versus subject tables that show, for example, references on rhinoceros behaviour or tapir ecology. Appendices, classifications of extant mammals and an index complete the book.

For research workers and postgraduate students this is certainly a stimulating book, full of data, correlations, extrapolations and provocative guesses. It is therefore dangerous material for the unwary or inexperienced, who may be unaware of the fundamental assumptions that Eisenberg's thesis is founded upon, and may be slow to appreciate the boundaries between correlation, extrapolation and guesswork.

Barry Cox is a Professor and Michael Stoddart a Lecturer in the Department of Zoology, King's College, University of London.

Life of the long-haired stars

David W. Hughes

Introduction to Comets. By John C. Brandt and Robert D. Chapman. Pp.246. ISBN 0-521-23906-0. (Cambridge University Press: 1982.) £21, \$45.

COMETS are heavenly bodies of considerable beauty, volatile character and deep physical and chemical significance. Their contents are fresh, thermally unaltered and undifferentiated, and the large outpourings of gas and dust that occur when the comet is close to the Sun often produce a coma and tail of truly astronomical proportion. Comets are also newsworthy. The past decade has seen the

blossoming of ultraviolet and infrared comet research; the next will see the launching of the first spacecraft designed to pass through the head of a comet and to gather *in situ* data.

Monographs on comets are scarce and there have been only three major ones since the turn of the century: G.F. Chambers's The Story of the Comets (Oxford University Press, 1910); R.A. Lyttleton's The Comets and their Origin (Cambridge University Press, 1953); and N.B. Richter's The Nature of Comets (Methuen, 1964—an enlarged translation of his 1954 book, Statistik und Physik der Kometen). We

now have Brandt and Chapman's Introduction to Comets. Let me say straight away that a very good introduction it is too; a worthy and timely fourth addition to the list. The authors have conveyed the excitement of modern comet work, the pace of the data flow and the originality of many of the new theoretical approaches. They are excellent recruiting agents for the subject.

The book starts by placing comets in the historical perspective and reviews many of our modern ideas about comets by discussing how scientists first approached, for

Halley's head, photographed on May 8, 1910, from the Hale Observatory.

example, cometary spectroscopy and the interactions of comets with the solar wind. The second section deals in depth with the dynamics and structure of comets and looks at the models that have been proposed for the chemical reactions and dust emission processes. The origins of comets and their decay into meteor streams are also considered. The third section reviews the enormous advances that have come from the investigation of some of the recent bright comets, such as Kohoutek, Kobayashi-Berger-Milon and West. It also discusses the possible spacecraft missions to comets. The last section briefly touches on comet germs and impacts, and the place of comets in literature and art.

The book is extremely well illustrated and delves into the nature of comets with sufficient detail to satisfy the average undergraduate and postgraduate reader. Those seeking more, are efficiently led to an impressive list of publications in the "suggested reading" section.

I think the authors have used their 246 pages most effectively. For my taste I would have put in more than three pages on origin mechanisms, and would have laid more emphasis on orbital evolution, decay process and size variation. Also the section on cometary missions seems to have been written long before the publication date, in the rosy times when NASA were still actively planning cometary missions. The people who *are* going to Halley in 1986 don't get a mention.

Progress and prospects in solar physics

J. C. Brown

Solar Active Regions: A Monograph from Skylab Solar Workshop III. Edited by Frank Q. Orrall. Pp.350. ISBN 0-87081-085-5. (Colorado Associated University Press: 1981.) \$17.50.

IDEALLY the trilogy of Skylab Solar Workshop proceedings would have progressed from the tranquillity of Coronal Holes through Active Regions to achieve its nexus in Solar Flares, thereby exhibiting the physical progression of solar phenomena. In reality even the comparative opulence of workshop funds, albeit a tiny fraction of mission costs, did not permit this degree of coordination. Nevertheless the substantial overlap of participant lists means that the three workshop volumes together contain useful interdisciplinary seeds for the solar activity student to cultivate. Benefiting perhaps from previous experience, this third volume is the most readable.

The editor opens with a thorough overview of workshop results from each of the five teams who contribute about two detailed chapters each. A recurring theme throughout is theoretical and observational modelling of static loops of which the corona is now held mainly to consist. It appears to be generally accepted that spectral analysis can shed only dim light on details of loop heating mechanisms, though scaling laws permit comparison of the magnitude of heating in relation to loops of different lengths and pressures. Aside from these static analyses, the work includes a lengthy theoretical discussion of gas flows and thermal instability in loops, complemented by two chapters on observations of dynamic phenomena at chromospheric/coronal levels and near the photosphere, the latter invoking data from OSO-8 as well as from Skylab

For the non-specialist the chapters of greatest interest will be those on theoretical coronal heating mechanisms and on spectral diagnostics, both of which are lucidly presented. The former contains much on energy release in plasmas which will interest plasma astrophysicists in general, while the latter concisely reviews the principles of spectrum line diagnostics for plasma temperatures, densities and differential emission measures. A frank assessment of progress made and of prospects for future work on active regions completes the monograph.

As usual this workshop raised more questions than it resolved, reiterating the stark solar message for cosmic astronomers of just how difficult astrophysical problems become when the object of study is close enough for detailed scrutiny. The Skylab Workshop series presented a unique opportunity for thrashing out both theoretical and observational progress in

important specialized problems. It is to be hoped that the sorry current state of NASA funding does not preclude such in-depth attacks on data from more recent missions such as Solar Maximum.

J. C. Brown is Reader in Astronomy at the University of Glasgow.

Sex differentiated

W.K. Whitten

Mechanisms of Sex Differentiation in Animals and Man. Edited by C.R. Austin and R.G. Edwards. Pp.603. ISBN 0-12-068540-X. (Academic: 1981.) £37, \$89.

In 1970, Harris and Edwards edited the Royal Society's discussion Sex Determination, and in 1972 a chapter by Short entitled Sex Determination and Differentiation appeared in Reproduction in Mammals, edited by Austin and Short, and published by Cambridge University Press. Now Austin and Edwards restrict their title to Sex Differentiation and argue that determination is the initial step in homotypic differentiation. But this is not accepted by some of their contributors, so the editors conclude that the argument is unresolved — a healthy attitude, emphasizing the need to standardize terminology.

This volume of 12 chapters written by specialists is intended as a text for advanced students and researchers. Lyon, Cattanach and Charlton give superb descriptions of testicular feminization, XY female wood lemmings, and sex-reversed and hypogonodal mice. The study of these conditions and the H-Y antigen, described by Wachtel and Koo, have contributed greatly to the recent explosion in our understanding of sex differentiation. There are excellent chapters on embryonic development and function, postnatal growth of gonads and sex characters from the clinical point of view, and the many defects in determination and differentiation in human beings. The structure of the gonad, however, is followed only as far as initiation of meiosis. I assume that this is because folliculogenesis and gametogenesis are covered in other recent books such as Peters and McNatty's The Ovary published by the University of California Press in 1980. There is a review of X-chromosome inactivation, but unfortunately no contribution by Ohno who anticipated many of the recent advances.

Benirschke adequately reviews freemartins and hermaphrodites of large animals, but his treatment of mosaics and chimaeras of mice is poor. Apparently he has not read Russell's Oak Ridge Symposium volume, Genetic Mosaics and Chimeras in Mammals (Plenum, 1980), nor the more recent work with fetal mouse hermaphrodites. These topics really deserved a chapter by Beamer whose BALB/CBea mice generate mosaic hermaphrodites by nondisjunction, or Eicher who has transferred the Y-chromosome of Mus poschiavinus to C57BL/6J-YPOS. This chromosome carries a variant of the testis-determination locus which interacts abnormally with autosomal or X-linked loci preventing normal testis differentiation even in the presence of H-Y antigen. Also there are excellent controls from consomic strains for these interesting animals.

The words "mechanisms" and "animals" in the title are misleading because some chapters, such as Stevens's account of his exciting spontaneous and induced teratomas, are purely descriptive, and except for a few pages of introduction and an excellent contribution on environmental and non-genetic mechanisms the book is restricted to mammals.

Reviewing this book has been difficult because many of the references cited, including books, are recent and not freely available in libraries with restricted budgets. There is no author index and the inadequate subject index appears to have been compiled from the table of contents. An editorial policy of giving the specific name when a species is first mentioned would have ensured entries for "man" and "mouse", at least in the species index, and eliminated some redundant ones. Surely textbooks warrant the services of professional indexers?

The editors consider the possibility of voluntary control of sex determination and doubt the "dire prognostications" that acquisition of this knowledge would upset the "fabric of society". Instead, they predict smaller, planned families and elimination of sex-linked disease, but conclude that no foolproof method exists at present. Already blastocysts can be sexed before implantation and fetuses of the unwanted sex aborted. Ironically, the early data from test-tube babies gave an excess of females (P<0.03) which might have been interpreted to mean that a procedure favouring girls had been stumbled upon. But I believe that biologists generally should require a probability of less than 0.01 before assigning significance, and this conviction has been supported by more recent results, particularly from Melbourne.

In spite of these criticisms I consider this a valuable and major work, updating Crew's little gem Sex Determination, published by Methuen in 1965, and fit to stand alongside White's Animal Cytology and Evolution (Rand McNally, 1973).

News of conception, pure and applied

C.R. Austin

Fertilization and Embryonic Development in Vitro. Edited by Luigi Mastroianni and John D. Biggers. Pp.371. ISBN 0-306-40783-3. (Plenum: 1981.) \$45, £28.35. In Vitro Fertilization and Embryo Transfer. Edited by E.S.E. Hafez and K. Semm. Pp.393. UK ISBN 0-85200-438-9; US ISBN 0-8451-3005-6. (MTP Press/Alan R. Liss: 1982.) £29.95, \$58.

THE recent upsurge of attention paid in the public media to the growing number of normal childbirths following the fertilization of human eggs in vitro, and the culture and reinsertion of the resulting embryos into their "mothers", must serve as welcome publicity for these two books, both of which provide in their own way the background to those newsworthy events. The publicity is a late development, for the vigour of scientific research in this field has been building up for the past 25–30 years, and the intellectual springs behind this drive are based on biologists' ambitions that go back a century or more.

Some of the history is discussed in the Prologue to the book edited by Mastroianni and Biggers, though this account is concerned primarily with milestones along the trail of the recovery and culture of mammalian embryos. From early times, investigators have been fascinated by the prospect that conditions might be achieved in the laboratory permitting the union of mammalian gametes and the ensuing development of the embryos in such a way that these events could be held under direct observation in vitro. Also early in the story, the remarkable resilience of mammalian embryos to experimental manipulation attracted devoted study, and the first successes with the transfer of embryos from one animal to another were achieved before the turn of the century. With increasing sophistication the focus has sharpened in the modern era so that investigators have become concerned more and more with fundamental details.

The two books under review have, not surprisingly, much in common. They are of about the same vintage, with that edited by Hafez and Semm marginally the older as it is based on papers presented at a world conference in 1980. The other is a "planned" book of 15 chapters (21 authors, all in American laboratories), while Hafez and Semm is comprised of 37 papers (71 authors, of whom 51 work in countries other than the USA, chiefly West Germany, France and Japan). The common ground of subject matter includes the recovery and preparation of gametes, in vitro fertilization, the culture and evaluation of embryos, and embryo transfer; differences arise from the manner in which the subjects are handled and in the identity of peripheral topics. Broadly

speaking, Mastroianni and Biggers is biased towards basic problems and Hafez and Semm towards the applied.

The former volume is distinguished by a monumental chapter by R. Yanagimachi on mechanisms of fertilization in mammals; this, together with three others (by G. Oliphant and L. A. Eng, B. D. Bavister, and D. P. Wolf), tells the reader almost all there is need to know about sperm maturation and capacitation, the acrosome reaction, penetration of egg investments, sperm-egg pronuclear life and the blocks to polyspermy - all this in laboratory animals. In vitro techniques are stressed. In addition, this book offers two chapters on gamete interactions and egg activation in the sea urchin (a worthy comparative background, though inessential in the present context), two chapters on chromosomal anomalies affecting embryonic development, two more on the rather esoteric topic of water and electrolyte balances in blastocysts, and finally a well planned and informative chapter on embryo transfer in cattle.

In Hafez and Semm, by contrast, no less than 14 papers describe the application of methods for in vitro fertilization, and four deal with embryo transfer. About half the papers in this book accord at least a mention to the human subject, for whom the timing of ovulation, oocyte recovery and maturation in vitro, fertilization in vitro and embryo evaluation are treated in varied but generally satisfactory detail, and the ethics of embryo transfer are briefly discussed. Curiously, none of the research groups that have reported full success with human material - well established pregnancies and normal births - are represented here. Other papers are concerned with non-human primates and farm animals. The book also fortunately provides us with Pierre Soupart's report, bringing us up to date with his work on initiating development by the singular device of fusing two oocytes; this may have been his last paper. In addition, there is a report on gonadotrophin production by baboon embryos in vitro from V.Z. Pope et al., and descriptions of two recently developed rapid assay methods for LH by M. Taymor et al. and by R. Frydman et

Both of these books are mines of information and "musts" for all gametologists; if only one is to be purchased the choice must depend on the predilection of the reader — whether for the basic or the applied, for the transatlantic or the international, or simply for the more or less expensive.

In search of the sublime

S. M. Walters

The Garden of Eden: The Botanic Garden and the Re-creation of Paradise. By John Prest. Pp.122. ISBN 0-300-02726-5. (Yale University Press:1982.) \$25, £12.50.

AMONGST the ever-growing literature on the history of gardens, relatively little explicitly treats of botanic gardens and their place in the general development of horticultural ideas and practices. It is therefore of some interest to note the subtitle of John Prest's book, and to see how far the text which accompanies the lavish illustrations lives up to the promise. The thesis of the book is interesting, even novel: he traces the idea (or more strictly ideas) of Paradise in Christian thought and imagery as reflected in the design of gardens through the centuries, and places the sixteenth and seventeenth century botanic gardens firmly in this tradition. Whilst it is easy to agree that Christian images and influences were powerful in gardening history, the thesis does not wholly convince, for it underestimates the scientific and instructional aspects of the work of botanic gardens.

As befits an Oxford historian, the author has chosen the oldest botanic garden in England, that in his university, to illustrate the shape and scope of early botanic gardens, but it is surely too parochial altogether to ignore Kew except for a single, oblique reference. The final chapter, which discusses the breakdown of isolation of the hortus conclusus in the new climate of interest in nature and the natural world, is surely the place where Kew Gardens cries out for treatment. The interplay of botanic gardens with the great private gardens of the nobility is indeed a fascinating theme, but it is curiously and disappointingly undeveloped in this book.

The relationship between the plants and the animals in the Garden of Eden — one of the splendid illustrations in colour (also used on the dust-jacket) depicts this scene painted by Jan Brueghel - is touched on throughout the book, with the strong implication that it was only the sheer impractibility of including animals that prevented botanic gardens from being also zoos. This is surely a serious distortion of the history of botanic gardens, which arose largely to satisfy the needs of medical teaching in the universities. Although it is true that botanic gardens later took on the general function of displaying as wide a range of plants as possible, there is no evidence that they were ever seriously troubled by the vision that they might also display a correspondingly wide range of

A second edition of Sarnat and Netsky's Evolution of the Nervous System has been published by Oxford University Press, price £9.95. The first edition was reviewed in Nature 252, 428; 1974.

representatives of the animal kingdom. Why should they, when systematic zoology was not taught in the universities, either to medical students or to anyone else?

It is perhaps inevitable that a book written by a historian on botanic gardens should say very little about the plants themselves, although they are the *raison d'être* of the institutions which grow them; when we find, however, that such few Latin scientific names as are used are mostly given incorrectly, with no capital letter for the generic name (as on pp.61 and 83), our confidence in the author's knowledge of this part of his subject is seriously undermined.

Undoubtedly, the author has read both widely and deeply in and around his subject, as the many footnotes, sensibly collected at the end together with the excellent bibliography, bear witness. As a source for further exploration of interesting themes, the book is quite exceptionally useful. The quality of paper, printing and reproduction of illustrations is very high, and the price, by 1982 standards, quite modest. A minor irritation is that many of the pages are unnumbered, because of the placing of illustration captions: this could surely have been avoided, without detriment to the very attractive design.

S. M. Walters is Director of the University Botanic Garden, Cambridge, and author of The Shaping of Cambridge Botany (Cambridge University Press, 1981).

Chemical soul

A.G. Lee

Liposomes: From Physical Structure to Therapeutic Applications. Edited by C.G. Knight. Pp.497. ISBN 0-444-80320-3. (Elsevier/North-Holland Biomedical: 1981.) \$110.75, Dfl. 260.

THE behaviour of suspensions of phospholipids in water (liposomes) has been under study for many years now, originally as a model for the lipid phase of biological membranes but more recently to investigate the possible therapeutic applications of liposomes in the delivery of drugs, enzymes and so on.

It was apparent by the late 1960s that the fact that lipids formed sealed vesicles when dispersed in water meant that they might be used to trap and protect unstable compounds from a harmful environment and so, for example, might enable the oral administration of compounds that would otherwise be inactivated in the gastro-intestinal tract. One possible advantage of

liposomes for such a role is that since they are composed of "natural" compound, they might be expected to have little biological activity on their own. It has not turned out to be quite so simple. The problems, and attempts to overcome them, comprise the second part of this book.

Unfortunately, liposomes have antigenic properties, described in a chapter by Scherphof and co-workers. Patel and Ryman discuss the fate of liposomes when administered to animals, and Finkelstein and Weissmann describe attempts to target liposomes to specific tissues. An obvious problem raised in several chapters is that for liposomes to act as efficient drug delivery systems, drugs must not readily leak out of them. As discussed by Knight, this can in part be overcome by designing hydrophobic pro-drugs which are more likely to remain associated with the liposomes. In part also, it can be overcome by choosing components for the liposomes which will minimize their "fluidity" Nevertheless, the conclusion reached by Fildes is that the application of liposomes in the pharmaceutical industry is a long way off, because of a wide range of technical problems. At their most basic, liposomes would not be expected to last for very long in the average bathroom cabinet.

The overall impression of the second half of the book is then, as far as therapeutic applications are concerned, that liposomes are an answer awaiting a problem. With the first half of the book, we are on much more solid ground. This sets out to describe the physical properties of liposomes, with the aim of providing the information necessary for the proper design of liposomes for therapeutic applications. I imagine, however, that the book will be read mostly by those with an interest in biological membranes. It does provide an excellent, non-technical summary of our knowledge of the lipid bilayer, although the lack of discussion of the effects of proteins perhaps limits its general interest.

As is proper, the first chapter is a general introduction by Alex Bangham, who has done so much to generate the current interest in liposomes. A chapter by Eibl describes the synthetic routes to a wide range of phospholipids that he has developed based on reactions of phosphatidic acid dichlorides. We then have chapters on freeze-fracture studies, differential scanning calorimetry, X-ray, NMR and ESR. The latter chapter, as is appropriate for ESR, has an aura of mystery about it — the journal volume numbers given as $c \ll 1$,

Finally, readers will have to decide for themselves whether or not Thudicum's description of lipids as "the centre, life and chemical soul of all bioplasm" (quoted by Bangham) is a little over the top.

A.G. Lee is a Lecturer in the Department of Biochemistry at the University of Southampton.

What place for social sciences?

Lord Rothschild's enquiry into the British Social Science Research Council seems to be complete but the report has not yet been written. Here is what he should conclude:

In many places social science is regarded as integral with science itself, under some such name as Wissenschaft. In Britain, by contrast, the social sciences have been regarded as studies apart and as studies that are inherently poor relations of the natural sciences. There has been a research council to support academic research in the social sciences for only the past two decades. During that period the Social Science Research Council has earned a mixed reputation. Like its counterparts elsewhere, it has found that many of the projects it has been supporting can easily be made fun of. It has also — and openly — proclaimed that part of its task has been to improve the quality of academic research in the social sciences. (In the process, inevitably, some of its functionaries have been persuaded to laughable pedantry.) Then, with the expectation that research should be useful, the research council had been asked insistently the old utilitarian question, "what use is it?". Nobody knows just which of these views persuaded Sir Keith Joseph, the Secretary of State for Education and Science, to let it be known that he is sceptical of the council and most of its works and, soon after his own appointment last September, to saddle Lord Rothschild with the task of pronouncing on the council's future. Perhaps he was simply counting on the likelihood that the man who caused ructions among natural scientists with his recommendations in 1971 for the reorganization of the other research councils would be equally subversive in the social sciences.

What, however, should he say? The first need is to recognize that the abolition of the Social Science Research Council would be intolerable. Whatever its hesitancy in the past two decades and its ways of working, the council has not merely established a number of important and productive academic groups in British universities, but it has substantially achieved that part of its programme intended to improve the quality of research in the social sciences. Moreover, especially at a time when the universities as such are less able than ever before to support research, the abolition of such a serious fund as the research council has become would create much more damage than the universities could sustain.

So, should the Social Science Research Council be reorganized in some way, and if so, how? In the past three years the council has been doing everything it could to make its procedures more understandable to those whose work it supports and at the same time to make its intentions more widely appreciated by the government and in the country at large. In the process the council has angered many of those who had grown used to the old procedures. Thus the council now finds that its critics are in two camps — those who preferred the past, and those who are unconvinced that its present procedures will deliver what people expect of the social sciences.

Nobody should be dismayed that this turn of events has come about. Who asks that a newly created organization such as the council should be able, within a couple of decades, to find a sure

US contributors please note

From now on, authors in the United States and Canada should send their manuscripts either direct to London or to the Washington office, whose new address in *Nature*, 991 National Press Building, Washington, DC 20045; manuscripts should no longer be sent to *Nature*'s New York office.

way of supporting research in the social sciences? The problems, acknowledged by everyone concerned at the outset, are too serious for that. And in any case, the successes in the council's portfolio of previously supported projects are quite sufficient to outweigh the hasty criticisms of those who point to projects that have failed. If some reorganization of the social sciences is needed, and it may be, attention should be directed to the present mismatch between what the council does in the support of academic research and the uses which government departments make of academic skill and research in the social sciences.

One of the most valuable parts of Lord Rothschild's declaration on the Social Science Research Council will undoubtedly be the calculation he will have made of the amount of research in universities commissioned directly by government departments and that supported by the research council. Paradoxically, the circumstances are the inverse of those that stimulated Lord Rothschild's recommendation of 1971 for the natural sciences. There, a decade ago, research councils such as those responsible for agriculture and medicine were free to decide for themselves what research strategy should be pursued, while the ministries most directly concerned were able only in passing to offer advice. The recommendation, immediately accepted by the Heath government, that in future (as now) the ministries should commission research in important areas from the research councils was sensible. The fact that the "customer-contractor" principle has not worked entirely satisfactorily is no fault of the principle, but of those who have tried to apply it. In the social sciences, on the other hand, the volume of research commissioned directly by government departments is far greater than that which the Social Science Research Council is able to support. Moreover, on the face of things, the projects commissioned directly by government ministries are put out to academic research groups with comparatively little advice from the Social Science Research Council, the body best equipped to tender an informed opinion. So is there not in the future organization of the Social Science Research Council, a need that the whole volume of public support for research in the social sciences should be channelled through some common agency?

The question remains of what should be the relationship between the social and the natural sciences. Academics, notoriously hide-bound, have over decades argued the toss about the place that social science should occupy in academic life. Economics is accepted, now, as an inevitable part of the spectrum of what goes on in universities. More esoteric subjects anthropology on the one hand, sociology on the other hand - are more easily scorned, but wrongly. Physicists may hold that the data on which people in these disciplines base their arguments, and the arguments themselves, are fuzzy by the standards that apply in, say, the analysis of data collected in some objective measurement of the real world. But was there not a time when even physics was a fuzzy field of speculation? Can it be right that the natural sciences should continue to laugh at the difficulties with which the social sciences must contend? For what the field needs is what the Social Science Research Council has been saying for the past twenty years is an essential part of its own brief — the general improvement of methods of teaching as well as of research that will, in due course, make social science accessible to a wider circle, and thus more useful.

"Freeze" frenzy hits US

Does the public demand for a nuclear weapons "freeze" reflect a basic shift of opinion?

Enthusiasm for a freeze on the production of nuclear weapons is sweeping the United States. Rallies and teach-ins abound, with participants waving pictures of Hiroshima victims and charts of death from "limited" bomb blasts. Students and faculty on many campuses are involved. So are physicians. Even in the southern states, which was fairly unmoved by the Vietnam protests, freeze frenzy is taking hold.

The movement has been accompanied by pronouncements from prominent people calling on the Reagan Administration to stop its weapons build-up, and blaming the arms control and national security community for giving the public gobbledygook and no results for its 20 years of effort. Historian Barbara Tuchman, whose ability to understand the intricacies of history has won her two Pullitzer prizes, threw up her hands in pages of the New York Times recently and confessed that "the subject of nuclear arms control . . . is virtually incomprehensible to the layman". She showed how arms control has failed since the beginning of the century. Meanwhile, Yale psychiatrist Robert Jay Lifton has blamed the intellectual community for not doing enough. "This central issue of our times has been fundamentally ignored in the universities", he said at a recent conference jointly sponsored by two education groups and Hobart and William Smith College. The failure of leaders and the security community was bemusedly outlined in public recently by a former participant, Roger Molander who after years working on nuclear arms control in the White House quoted a presidential science adviser as saying, of the leaders' behaviour "where are the grownups?" Molander quit and founded "Ground Zero", a grass-roots organization that has been remarkably successful in sparking rallies around the land.

Are we witnessing a fundamental shift in US opinion? Europe is watching it closely, particularly the European peace movement, which is hoping that it will dissuade the Administration from its hawkishness, and perhaps tip the balance against NATO plans to install new missiles in Europe.

But the shift may not be fundamental. It is caused by two things, both of which can change quite soon. First, the President and Mr Caspar Weinberger, Secretary of Defense, and other officials, have been saying things in public that previous Administrations were wise enough to avoid. They have talked openly, and casually about the likelihood of nuclear war, the "fact" of Soviet military superiority, the need for a gargantuan, apparently ceaseless weapons build-up, and they have appeared patently insincere about arms control. By escalating public discourse, clearly they are upsetting people.

The second cause of the freeze frenzy is the volatility of public opinion itself, which is now swinging back from its hawkish mood of recent years. The last time a serious arms control plan was presented to the public, SALT II in 1979 and 1980, they were clearly bored. Then the humiliation in Iran, and Soviet invasion of Afghanistan, sparked a conservative trend which eventually brought Reagan to office. If the public is asking why, today, there is not sufficient arms control, it has itself, in part, to blame.

European peace movements should realize how different the American freeze movement is. The US demonstrators seem not too concerned about the proposed emplacement of Pershing and cruise missiles in Europe — the 1979 NATO decision which Europe's peace movement wants reversed. To the Americans, those Pershing and cruise missiles are small fry compared with Reagan's plans for the MX missile and an apparently ceaseless parade of giant aircraft carriers, submarines, nuclear-armed B-1 and Stealth bombers, and the like which the American movement seeks to freeze. Nor is the neutron bomb a major US issue. The two movements have not fused, although some major gaffe by the Reagan Administration could yet cause it to happen.

And Americans should question whether their intellectuals are

to blame - whether, as Lifton grandly said, "a generation of scholarship has been lost" — whatever that means. To blame the arms control and national security intellectuals for the military build-up in the world is like blaming social scientists for the persistence or racism, poverty, and violence. True, one of the vanities of intellectuals is that they think that by studying a subject, they can control it. But not even scientists can do that. William Perry, former Under-Secretary for Defense Research and Engineering, and one of the key defence intellectuals who tried to "sell" SALT II for the Carter Administration, says there is "some merit" in the view that US defence intellectuals have failed the country. But it was the public's fault too, he notes "very little else at the time (besides SALT II) was guaranteed to put the public to sleep". Perry welcomes the freeze movement although he disagrees with some of its aims. "As a leader in an Administration I would rather work with an aroused public, and try to channel that interest, than have to try to convince an apathetic public.'

It would be unwise for the Reagan Administration to view the freeze frenzy as a suspect foreign import, festering on US university campuses, and accuse its adherents of lack of patriotism. While the movement has set itself against the Administration's arms build-up, it would clearly be delighted by any presidential move to talk seriously about arms control with the Soviet Union. For the first time in years arms control is gaining a public constituency in the United States. It is too bad that SALT II is not before the Senate, so that the United States, Europe, and the Soviet Union, could benefit from it.

Hasty abolition

Disappearance of the Schools Council was predicted, but may have been unwise.

The British Secretary of State for Education and Science, Sir Keith Joseph, is plainly an abolitionist by temperament (see preceding page). Hankerings to get rid of the Social Science Research Council are one thing. Last week, however, he abolished the Schools Council, an organization set up in Britain in the 1960s in the hope of overcoming some of the obstacles to national planning in British schools education. For in Britain, as elsewhere, the central government has no direct authority over teachers in local schools, who are employed by and responsible to their local education authorities. The result is that the curriculum can vary enormously from one place to another; school leaving examinations can differ in stringency from one examinations board to another; and in principle there is no reason why some local authorities should not give their schools entirely eccentric marching orders. The problem of bridging this gap has daunted many governments and yet is politically insoluble — the local authorities in Britain would not sacrifice such independence that they retain in this small area of their operations.

The Schools Council was designed principally as a talking shop, a place where central government, local government and independent people could be represented and in which, tacitly at least, local authorities and the central government would come to some understanding on education policy. What has gone wrong is that the Schools Council's procedures have become cumbersome and the council itself has been politicized by the conflicting interests it represents, often those of a teachers' labour union. At the same time, the original plan to bring about some coherence in British schools education by advising novel and more stimulating curricula has been defeated by the shortage of funds and, to some extent, by the apathy of the schools. The Schools Council has in the past few years been a sitting duck, ripe for abolition. Sir Keith Joseph has done this deed and now plans to replace the Schools Council by two advisory bodies, one for the curriculum and one for examinations. The snag is that these advisory bodies will not, by their constitution, bring central and local government together. When he is more experienced in his present post, Sir Keith Joseph will regret this.

US biomedical research threatened

New director at NIH faces discontent

Washington

The primary sponsor of US biomedical research, the National Institutes of Health (NIH), is at last, after a ten-month hiatus, getting a new director. He is Dr James B. Wyngaarden, whom the Administration and the biomedical community agree is a good choice. Wyngaarden had his Senate confirmation hearing last week and is expected to be confirmed and sworn in within the next few weeks. But he will be inheriting a storm.

When Wyngaarden moves in to NIH's blossoming campus on the fringes of Washington, he will have to face the anger of deans and administrative officers of the 2.500 medical schools and universities in the United States who receive NIH funds and who are furious with NIH for proposing to cut their indirect cost allowance by 10 per cent in 1983. Although the immediate sum involved is a trivial \$70 million in NIH's proposed \$3,700 million budget, the administrators fear that the cut portends a fundamental shift in the structure of the US university economy. Whether it does or not depends on Congress, which may yet restore the money.

Wyngaarden, 57 and a Democrat, is Hanes Professor of Medicine and chairman of the department of medicine at Duke University School of Medicine in North Carolina. Among other Washington assignments, he has served on the President's Science Advisory Committee. His nomination was backed by NIH's many supporters on Capitol Hill, and by Richard S. Schweiker, the chief of NIH's parent Department of Health and Human Services, who is himself a former congressional backer of NIH. Although some of the Reagan Administration's key science appointees have included unknowns or outsiders to the basic science community, Wyngaarden is neither.

Wyngaarden's first job will be to find directors for the five NIH institutes which are without permanent directors, some since January 1981. Another key post, that of deputy director of NIH for science, is also vacant. The previous director, Donald Frederickson, drew up lists of candidates last July, and Wyngaarden will have to see how many candidates are still interested in the jobs. In federal research agencies, when a permanent chief is lacking, normal business continues. What suffers is the organization's internal needs and long-term planning.

Wyngaarden inherits a dispute over indirect cost allowances that is dividing university administrators and faculty across the country. The bulk of NIH funds for research project grants and research centres is awarded in two parts. The first part is the direct cost of the research salaries, equipment, travel, publications, and the like. The second part covers indirect costs, a percentage of the direct costs that the government agrees to pay to the researcher's home institution to keep him housed. Indirect costs include such things as central fuel and electricity bills, cleaning, library and central animal facilities.

Previously NIH reimbursed the institutions a fixed 15 per cent of a researcher's direct costs, no matter what they were. However, this was deemed arbitrary and NIH allowed the percentage it would repay to grow, frequently reassessing it to take account of rising utility costs and inflation. For 1983, NIH estimates that indirect cost payments on research grants and centres will average 30 per cent of the direct costs. Other federal agencies that fund research follow the same process but with percentages that vary among agencies and universities. (The

resulting patchwork of repayments would be unbearable for university administrators were the funds not essential for their hard-pressed institutions.)

Thus, while the growth in research budgets has tended to slow in recent years, indirect costs have kept on rising. A Columbia professor estimated recently that fifteen years ago his research supported by NIH enabled Columbia to collect \$2,000 in indirect cost repayments. During that time, even though his research effort has only doubled, Columbia has been able to collect \$40,000 in indirect cost reimbursements on it.

However, the array of administrators and their representative societies, such as the Association of American Medical Colleges and the Association of American Universities who oppose the NIH plans to reduce its contribution to administrative costs, are not merely concerned about paying next year's heating bills. They claim that NIH is shifting the whole debate about what the institutes are for and how they should maintain US world leadership in biomedical research.

During his six years as NIH director, Frederickson argued that researchers suffered from uncertainty as to what would

Franco-Soviet space flight plea

Three pressure groups of French scientists and intellectuals, "Comité des Physiciens Français", "Comité Sakharov" and "Solidarité au Spacionaute", have called for France to withdraw from the Franco-Soviet manned spaceflight planned for June.

Following the procedure of the manned Interkosmos flights, which included representatives of all Comecon block countries, two French candidates for space — Jean-Loup Chretien and Patrick Baudry, are now training in the Soviet Union. One of these will be selected to be launched with a Soviet partner to rendezvous with and work aboard the Salyut-7 space station put into orbit last week.

The pressure groups base their demand on the recent increase of human rights violations in the Soviet bloc — the invasion of Afghanistan, the banishment of Sakharov, martial law in Poland. For a relatively minor scientific gain, they say, France would be reduced to a "supernumerary" in a Soviet public-relations spectacular. The propaganda value to the Soviet Union of a joint flight involving, for the first time, a guest from outside the Socialist bloc, would be immense.

For all three groups agree that at this stage France stands to gain little from the proposed manned flight. Franco-Soviet cooperation in space goes back to the visit of President de Gaulle to Baikonur in 1966,

and over the years has included a laser ranging experiment on the lunokhod Moon-rover, gamma ray spectrometers carried aboard Venus probes, and the launching by the Soviet Union of the French Aureole geophysical satellites. French participation is also planned in the Soviet mission to Venus and Halley's comet in 1985.

The proposed French participation in the Salyut mission would cover three main fields, astrophysics, materials sciences and biology. Comité de Physiciens Français, in particular, contends that the first two programmes could be carried out equally well aboard an unmanned automated spacecraft. As for the biology programme, this will simply allow the "well-known" physiological stresses of space to be applied for the first time to a French citizen.

Vera Rich

happen to the research budget from one year to the next. This discouraged bold thinking and long-range research plans, he said.

According to Frederickson, NIH should fund 5,000 new "noncompeting" research project grants, in addition to keeping previous years' commitments to projects lasting two and three years. In this way, researchers would know there would be 5.000 research project grants available for the best proposals. As a corollary, Frederickson proposed that training grants should be stabilized, with the budget allowing for 10,000 of these, each year. The numbers were arbitrary and widely known to be a budget ploy, but they had the salutary effect of keeping everyone's attention on a few key concepts for the health of research: stability, availability of money for new projects, encouragement to young researchers.

Sources close to the NIH budget process say, however, that last December, when NIH received a 1983 budget figure, it calculated that it would allow funding for only 3,500 new research project grants, embarrassingly far below the 5,000 goal publicized by Frederickson, and well below the 4,741 new project grants funded in 1982. Schweiker therefore told NIH to change the budget, keeping the same total, so that the number of new project grants would be above 4,000. As a result, NIH proposed taking the cut in the administrative side, in direct costs, to avoid an enormous fight with scientists claiming that NIH was abandoning its commitment to innovative research.

So now the universities and research institutions are asking why they should be singled out for cuts — and what Pandora's box has been opened for future years.

According to John F. Sherman, former deputy director of NIH and now vice-president of the Association of American Medical Colleges, which protested to Schweiker in March, it is likely that the 10 per cent cut proposed for 1983 will set a precedent for unpredictable cuts in NIH's indirect cost allowances in future years, and perhaps lead to a lowering of indirect cost allowances by other federal agencies.

"If there is anything to divide faculty from academic administrators, this is it", says Sherman. "The institutions' representatives are frantic. They see no solution except for Congress to add the money. Whereas the faculty are more willing to see indirect cost reimbursements cut in order to maintain a higher number of competing research awards."

If NIH's indirect cost reimbursements are cut, however, institutions may be forced to reduce the size of their research programmes. And if NIH awards fewer research project recipient grants, the institutions will have a smaller base for seeking indirect cost payments. To hear them talk now though, the two sides seem not yet to have realized that they have a common cause.

Deborah Shapley

Commercialization of research

Patent views

New York

Close on the heels of the closed meeting of five prominent university presidents at Pajaro Dunes, California, last month (Nature 8 April, p.479), the first of many other, open meetings was held last week in New York to discuss the growing issue of commercialism in academic research. This one was sponsored by the New York Bar Association's patent committee. Participants included Dr Steven Muller, president of Johns Hopkins University, Joshua Lederberg, president of Rockefeller University and A. Thomas Bartlett, president of the American Association of Universities (AAU).

The participants concurred with the conclusions of the Pajaro Dunes meeting concerning the problems of the commercial use of university-based genetic engineering research. In the words of Dr Muller, "the hazards to universities are manageable". It seemed clear at the meeting, though, that there can be no sweeping, general rules covering every campus and field of research in the nation, and that university policies will be built up step-by-step.

Those at the bar association meeting felt that university faculty would be well able to defer publication of key research in the open literature to satisfy patent needs of the commercial partners. Dr Lederberg noted that while such delays are "natural hindrances" to normal university activity, they should be acceptable to faculty so long as delays are reasonable. Dr Muller pointed out that Johns Hopkins recently passed regulations requiring university researchers to publish in the open literature and to discourage undue secrecy while faculty file for patents. The new regulations also place the burden of proof on faculty members who claim that a private invention has no relation to their university work.

One problem highlighted in the discussion was that European visitors to US campuses could pick up innovations in the course of seminars and talks with US scientists, go back to Europe and patent them, leaving the US academic inventor of the idea with no protection. This possibility arises because European law awards patents to the first to file for one, who may not necessarily be the inventor as in American law.

There was a call at the New York meeting for a re-examination of the relationship of professor to university and the traditional rights of university employers and their faculty employees, often ignored in faculty contracts. For example, can a university pressurize one of its professors to pursue a patent if he is reluctant to do so?

Dr Lederberg encouraged universities to help their faculty negotiate their outside contracts and to define extramural and intramural roles. He was concerned that many faculty are under-selling their services, and recommended that they charge six times their academic rate of pay for outside consultation. The universities can benefit, he said, by arranging that these fees be shared equally between a faculty and member and the institution.

Finally, several details of the best known university-industry agreements are now available to university presidents seeking to negotiate their own industry arrangements. University presidents seem to be making a practice of circulating current or draft agreements with industry among themselves for purposes of comparison.

Last year, Representative Albert J. Gore (Democrat, Tennessee) attacked the universities for their new industry ties and asked AAU to establish general guidelines on the matter. But the New York meeting seemed to confirm that such general guidelines are unlikely to emerge, or be seen as practical. As AAU president Bartlett said, "we are groping our way into the future".

Dutch pharmaceuticals

New era vaccine

Waalre, The Netherlands

Intervet International, a Dutch veterinary pharmaceutical company, claims to have marketed the first vaccines produced through recombinant DNA technology. The Dutch are proud to have beaten two American companies — Norden Laboratories and Cetus — which recently announced that they were developing a vaccine against pig scours for introduction on to the market within two or three years. Intervet marketed two scour vaccines at the end of March.

The vaccines are intended to prevent infectious diarrhoea of pigs and calves, a major cause of which is the Escherichia coli bacterium. The bacterial components implicated in causing scour in pigs and calves are the adhesion factors K88 and K99 respectively. Combination of these factors with a special adjuvant was used by Intervet to produce a vaccine which, when given to the sow or cow, causes the animal to produce protective antibodies which are passed on to their offspring through the colostrum or first milk. In the past adhesion factors K88 and K99 have been purified from wild strains of bacteria isolated from the field. Using cloning techniques Intervet transferred the genes responsible for the production of the K88 and K99 into a laboratory strain of E. coli (K-12) which then produces a much greater quantity of antigen for the preparation of the vaccines.

The work to produce these strains started in 1979 in collaboration with the Dutch Institute of Health and was later transferred to the DNA research group within Intervet's mother-company Akzo Pharma, itself part of the Dutch chemical multinational Akzo. Casper Schuuring

Environmental research funding

Bleak outlook

The UK Natural Environment Research Council (NERC) is struggling against the somewhat cool attitude of the Minister of State for the Environment, Mr Michael Heseltine, towards science. The Chief Scientist's office at the Department of the Environment (DoE) is doing its best to protect NERC from budget cuts, but the task is not proving easy.

In fact, the department's attitude was so discouraging late last year that even NERC's chairman, the sanguine Sir Hermann Bondi, was beginning to be worried. When Bondi took up his post in October 1980 he defended those of Heseltine's cuts which were already affecting NERC, in the name of the "Rothschild principle" - that the customer (in this case DoE) pays for what it wants and the contractor (NERC) provides it. After more than a year's experience of DoE attitudes, however, Sir Hermann's line has softened a little: "I still believe in the Rothschild principle" he says, "but Rothschild assumed that there would be enlightened customers taking a long view".

The problem for NERC does not seem to lie in fundamental, or in applied research, but in the "strategic research" which is not obviously one or the other. A prime example is the geological survey of Great Britain, whose science may appear to be uninspiring, and which is applied only occasionally for major construction projects. In the long run, however, it provides a basic data set without which much other work would not be possible.

DoE's attitude has pushed NERC into finding more commercial contracts both in the United Kingdom, and abroad; but, say NERC staff, contracts in the United Kingdom cannot supplant the geological survey because they are too patchy, too specific and often entail a degree of commercial secrecy. Moreover, British firms are at least as short of cash as the government at present. Abroad, NERC have been seeking contracts actively, but without any major successes. Bondi would like to encourage this kind of expansion, but NERC is relatively new in the field and must compete with seasoned operators like the US Geological Survey and the Institute du Physique du Globe of Paris.

In the meantime, NERC staff must be supported — and the problem has been compounded by DoE delays in defining a programme of research for 1982-83. By early April, NERC would normally have expected to know DoE's requirements for the year. Worse, the council has been told not to spend money on the basis of DoE "letters of intent" until everything is signed and sealed, a further break with the usual practice.

However, there is some light at the end of the environmental tunnel. Recently NERC held a top level meeting with its three main

customer departments, those of energy, industry and environment and with the Central Policy Review Staff (the Cabinet's think tank) and there was a consensus that the problems lay with strategic research and long range planning.

NERC staff argued that if only they could be told the requirements of the departments well in advance, then the council could design a good basic and strategic research programme which would also yield the contractual results that the departments wanted. So the departments will work together to produce a five-year forward look for NERC, with the intention that this would be "rolled forward" annually thereafter.

Robert Walgate

NERC stays afloat

The British government has allowed the Natural Environment Research Council (NERC) one present: a new ship, specially designed for research, to replace Shackleton which is now a creaking 28 years old. The vessel is being bought on a loan from a merchant bank, and will cost NERC about £1 million a year for eight years out of its current £56 million budget.

The ship will be called *Charles Darwin*. It will not be ice strengthened, but will have a clear aft deck for equipment and will be able to tow over the stern, a big simplification over *Shackleton* (a converted container ship) which has to pull equipment from an A-frame over the starboard side. The *Charles Darwin* will be fitted for general research from marine biology to geophysics, and will provide the largest on-board laboratories of the NERC fleet. It should be delivered in 1984.

The research fleet will then include: Discovery, also a general purpose research ship, which must retire around 1989; the marine biological ships Frederick Russell and Challenger; and two ice-strengthened vessels. There are three other English research ships owned by the Ministry of Agriculture, Fisheries and Food (for fisheries research).

US recombinant DNA guidelines

Expected change

Washington

Continuing the trend towards relaxing controls on the newly commercial business of recombinant DNA research, the National Institutes of Health (NIH) has published revised guidelines that govern most US academic research and some industry research in the field. There are few surprises in the new guidelines; they follow the plan voted by NIH's Recombinant Advisory Committee (RAC) meeting in February (see Nature 4 February, p. 358).

The revised guidelines (published in the

Federal Register, 21 April and effective from that date) contain three important features. First, although there was pressure to abandon the present system of mandatory controls and change to a voluntary system, the mandatory system was retained. This means that organizations performing recombinant DNA research must still each have an institutional biosafety committee, and, for those doing work at P3 and P4 containment levels, a biological safety officer.

Second, no class of experiments is "prohibited" any longer. Of the five classes of experiments that were prohibited under the old guidelines, three are still required to undergo RAC review and NIH approval before initiation. These are drug resistance traits, toxin genes and deliberate release to the environment. Third, the section of the guidelines dealing with containment levels has been drastically simplified. Many experiments previously requiring NIH approval now require only the approval of the local biosafety committee.

In approving these guidelines, Richard M. Krause, Director of the National Institute of Allergy and Infectious Diseases of NIH, rejected a proposal for far greater relaxation of controls put forward last April by Dr Allan Campbell and Dr David Baltimore. These would have required a major overhaul of the guidelines. Apparently, Krause agrees with the majority of the members of RAC that such an overhaul is not appropriate — yet.

Deborah Shapley

UK nuclear power

Cracks no worry

New design criteria for the pressure vessel for a British pressurized water reactor (PWR) has been given the cautious approval of Britain's most distinguished PWR opponent, metallurgist Sir Alan Cottrell, now Master of Jesus College at the University of Cambridge.

The new criteria are the result of the work of the United Kingdom Atomic Energy Authority study group, headed by Sir Walter Marshall, on the integrity of PWR pressure vessels. The group last reported in 1976, but six years later the situation requires a fresh look. The design of the Sizewell PWR is going ahead; there have been changes in methods of steel manufacture; and there is now an accumulation of evidence and experience of stress corrosion cracking and of catastrophic failure tests.

In an open letter to Sir Walter Marshall, Sir Alan writes: "I would expect us to avoid the problems of localized cracking, underneath the stainless steel cladding, which the French have experienced in some of their vessels".

He adds "Whether we shall be entirely clear of the problems of metal fatigue and crack growth associated with corrosion is less certain, but the evidence now is far better than it was in 1976 and I agree with the report and you that it shows that crack growth rates are — or can be, if the quality of the metal and the water chemistry are closely controlled — much lower than appeared to be the case in 1976".

The report estimates that a hidden crack in a pressure vessel would have to be at least 75 mm in "height" to initiate crack propagation under normal operating conditions. ("Height" is defined in the report to be the vertical distance from the surface between the nearest and furthest surfaces of the crack.) The best estimates of stress corrosion crack growth indicate that cracks of a starting height of, say, 50 mm, would grow less than 10 mm during service.

The report also describes methods by which cracks can be prevented and monitored during the manufacture of the pressure vessel and during service, and in these respects, says Cottrell, the report goes much farther than its predecessor.

However, in the end Sir Alan remains very cautious. "To summarize", he writes "provided the recommendations in the report are all accepted and fully applied in practice; and in particular that arrangements are made to keep all parts of the pressure vessel in the 'upper-shelf' range of fracture toughness at all times; and arrangements are made to ensure that the vessel is free at all times from cracks, down to a size at which growth becomes insignificant under all conditions; then a PWR pressure vessel subject to all these conditions will have a high integrity and reliability in service". Robert Walgate

University redundancies

Now the crunch

British universities seem well on the way to solving their budgetary problems by persuading tenured academics to opt for early retirement. Hundreds of applications to retire early from members of teaching staffs have already been accepted. But many universities are left with the nagging doubt that the terms agreed with academics willing to go early may not qualify for reimbursement under the scheme the University Grants Committee (UGC) has now made public.

In February the UGC confirmed that it would reimburse in full the cost of payments to staff made redundant because of cuts in the government grant. In the UGC's letter to the universities, the term "redundancy" covered early retirement. For academic staff over 50 the approved terms are those of the Premature Retirement Compensation Scheme (PRCS) of the University Superannuation Scheme (USS) introduced in 1979. An eligible employee receives the USS pension and any accrued benefits plus a compensatory pension and lump sum payment calculated in "Scheme" years. The cost to the university

is the cost of paying into the pension fund this extra benefit.

The scheme allows academic staff below the age of 50 — not covered by PRCS — to receive a deferred pension, a lump sum payment of one month's pay for every year of service, and one month's pay for every year of service in excess of five years or after their 30th birthday, whichever is the greatest. Payments of up to £55,000 plus pension rights could be made to a redundant 50 year old. The scheme is essentially that put forward by the Committee of Vice-Chancellors and Principals except that the pensions of staff aged 50–55 who opt for early retirement will not be index-linked.

Conditions for reimbursement are stringent. The PRCS was not formulated as a redundancy compensation scheme and universities offering enhanced terms will not be repaid. Terms negotiated before 5 February will, however, be supported but only up to the limit of the government-approved scheme. Staff cuts must also be "consistent with academic plans" — UGC may refuse to pay out for redundancies which do not form part of a comprehensive economy drive.

Volunteers for redundancy schemes will have a good chance of being re-engaged for part-time teaching. The UGC will not reimburse for staff who are to be replaced, but recognizes the need to make a gradual adjustment to staff losses. The cost of taking back staff on a part-time basis will be reimbursed only if contracts are signed before the end of the academic year 1984–85 and do not extend beyond three years.

How are the universities coping with the cuts? Salford is hoping to lose 500 staff members (120-145 of them academic) by the end of the academic year 1984-85. Twelve of its 45 professors are to leave by September, and in order to maintain a balance of experience and age distribution the university is keen to get voluntary severances from younger staff.

Leeds was one of the first universities to respond to government cuts by planning staff losses and it is hoping that its enhanced retirement scheme will make it eligible for compensation. Of the 145 applicants, 95 will have been accepted for early retirement. The bulk of staff losses were accepted under the first stage of its economy plan — a 6 per cent cut in expenditure by the end of the academic year 1982–83, but cuts to its budget and the repercussions of the government's overseas students policy have now forced a 10 per cent reduction in expenditure.

At the University of Cambridge there are doubts as to whether the university's plans will be eligible for UGC compensation. Forty academics have responded to an appeal to take early retirement. A scheme providing enhanced compensation was offered to university staff aged 58 to 60 after its approval by the Council of the Senate in February. The university hopes to attract 100 volunteers in a drive to knock £2 million a year from its expenditure by

July 1984. The university has had to offer enhanced terms because, compared with the age of 65 on which the PRCS scheme is based. Cambridge academics have tenure until 67. Eligible applicants will receive a full pension plus a lump sum calculated on the basis of the pension they would have received at normal retirement. The university is pleased with the response so far.

Jane Wynn

UK biotechnology

A start in sight

The British government has at last fulfilled its promise, made more than a year ago, to establish machinery for coordinating the national effort in biotechnology. Last wek, Kenneth Baker, the minister for information technology, announced the setting up of an interdepartmental committee on biotechnology under the chairmanship of Dr Ron Coleman, the recently-appointed Government Chemist.

Dr Coleman's chairmanship may seem rather unusual, chiefly because the Laboratory of the Government Chemist of which he is head, has traditionally followed a fairly narrow remit of providing analytical services to the public sector. But Dr Coleman's desire to broaden its scope has persuaded the Department of Industry to make the laboratory responsible for the department's interest in biotechnology. The new committee's membership includes all those government departments with an interest in biotechnology together with the medical, agricultural and science and engineering research councils, the British Technology Group, the Public Health Laboratory Service and the Centre for Applied Microbiology and Research, Porton Down.

The chief task of the committee, which will have no money of its own, will be to coordinate its members' separate interests. One question close to its heart will be how to transfer the results of biotechnological research into industry. That will involve paying special attention to the role of the Biotechnology Directorate, recently set up by the Science and Engineering Research Council, and the British Technology Group, whose task it is to exploit academic research in industry.

The committee's other main objectives are to foster international collaboration in biotechnology and to look for ways of ensuring the continued existence of culture collections, which at present suffer from being funded from a variety of different sources. The committee, which has before it a study commissioned by the industry department on the organization and funding of culture collections, will be looking for one government body to take over their administration and may recommend changes to the fees now charge for the services provided by the collections.

Judy Redfearn

French universities

Into reverse

One of the first steps towards undoing the authoritarian reforms of the French university system introduced by the previous minister of universities, Alice Saunier-Séîté, has just been taken. Students have been allowed back onto the university councils, the senior administrative councils of the universities.

The reform would be radical — if the students were radical. But the present atmosphere is nothing like that of 1968. The new student representatives are conservative and unreforming, say university staff. For example, in one recent meeting in the University of Paris, students warmly approved a proposal for more examinations and greater selectivity — something which would have been anathema fourteen years ago.

The underlying question is not what the students will do, but where the government will stop in this new attempt to restructure French higher education. M. Alain Savary, the minister for national education (which now includes the universities and grandes écoles), has some plans which are causing shivers in the French establishment. Not least among them is that the classes préparatoires, the usually private courses that prepare students for entry into the prestigious grandes écoles, should be put into the hands of the universities.

This would mean that the brightest of French schoolchildren, who normally pass through the classes préparatoires on their way to the grandes écoles (and thence to management and government administration), would be exposed to a university environment. There they would learn that the universities were not the second class establishments that some suppose, the argument goes, and some might even choose to stay and read for university degrees.

However, such proposals are too radical for the *grandes écoles*, who are resisting them so strongly — and are so well represented in government — that the political will at the ministry of education is beginning to falter.

For researchers, the situation is even more complicated. There is a conflict afoot between the minister for research and technology, Jean-Pierre Chevenement, and M. Savary. Chevenement has battled long and hard for control of all government spending on civil research and development. Much of the research is done in the university environment, in laboratories which are now funded by Chevenement's ministry. In general, the researchers in these laboratories (such as those of the Centre Nationale de la Recherche Scientifique) do little formal teaching in the university (although they help to train researchers through seminars and research degrees). Chevenement is believed to want more of the teaching to be done by his researchers,

to improve the training of scientists; but this would remove some of the university teachers' higher level and more interesting work. So university opposition is growing to these moves, and Savary inevitably represents one side and Chevènement the other.

How this battle will develop is anyone's guess, but it could easily lead to another deadlock, when the promised higher education reforms would merely tinker with the system, rather than removing its two main faults: the class divisions between the grandes écoles and the universities, and between the researchers with formal teaching responsibilities and those without.

Robert Walgate

Moves on energy

The French government is showing every sign of pain in its attempts to embrace the environmental movement. In the latest agonies, the council of wise men which advises the Minister of Industry on nuclear safety has been reformed to include a few token nuclear opponents; and the promised new agency for renewable energies is to be set up, but shorn of FF 170 million.

The safety council is the Conseil Supérieur de la Sûrété Nucléaire, presided over by Professor Louis Néel, an ex-director of the French atomic energy agency laboratories in Grenoble. Néel is described by his opponents as "totally pro-nuclear" and, indeed, his council has met only three times in the past seven years, giving the previous government a pretty clear run on safety matters. Under the new arrangement, Néel stays as president of the council, but it is to meet more frequently (two or three times a year) — and there will be a few cuckoos in the nest.

These come in part from the addition of a further seven experts in the council, including a science journalist, M. Serge Berg of Agence France Presse. The biggest change, however, is the inclusion of trade union representatives on the council for the first time, among them Bernard Laponche, a prominent nuclear critic from the more environmentally inclined of the two major unions, CFDT. So far Laponche is not impressed. The council is still not complete and no date or programme has been set for its first meeting.

As for the renewable energy agency, Agence Nationale pour la Maitrise de l'Energie (ANME), this will regroup the existing solar energy and energy conservation agencies, and control their budgets; but present indications are that its budget will be less than the sum of its predecessors. The cut in budget is largely the result of a deal to buy Algerian natural gas – the energy conservation agency loses FF 170 million (£17 million) to help pay for the gas.

Radioactive waste in India

Looking to glass

New Delhi

The world's second commercial plant for the immobilization of radioactive wastes from nuclear power generating stations is soon to be built at Tarapur, in the western Indian state of Maharashtra. The first such plant is already in operation at Marcoule in France.

The new plant is being set up in the wake of increasing concern in India that radioactive waste from nuclear power installations might damage the health of the people — although there has been no scientific evidence of such damage so far from India's two nuclear power plants at Tarapur and Kota in Rajasthan state.

The radioactive waste immobilization method being adopted at Tarapur is a semicontinuous process which incorporates the oxides of high level waste from fuel reprocessing into borosilicate glassy matrices. The nominal throughput of the plant is about 25 litres of waste an hour, equivalent to the immobilization of wastes produced from reprocessing about one tonne of spent fuel a day. The plant would produce about 125 kilogrammes of glass a day, which is to be stored in stainless steel containers.

The process was developed in India and differs in many respects from the British and French techniques. The wastes are first calcined with glass fines in a process canister and then melted into a glass form. After sufficient "soaking" to help achieve homogeneity, the glass is cast into storage canisters — which can be inexpensive containers as the glass waste is more easily stored than liquids.

The storage units are stored in an engineered near-surface facility where they undergo continuous natural draught cooling to dissipate the decay heat under constant surveillance. The plant is designed to provide cooling for 20 to 30 years and incorporates facilities for establishing the characteristics of the waste products when the time comes for ultimate disposal.

The ultimate disposal medium has not yet been chosen, although current research favours a hard rock formation such as gneisses or granite.

The high-level radioactive wastes arise from the reprocessing of spent uranium fuel for the extraction of plutonium. The Atomic Energy Commission now proposes to build a chain of reprocessing plants in the country near the sites of future nuclear power stations. The proposal follows the United States' refusal to provide enriched uranium for the Tarapur nuclear power plant unless India meets conditions specified by the United States in the name of nuclear non-proliferation. Plutonium extracted by the reprocessing of spent fuel would therefore substitute for supplies of enriched uranium withheld in this way.

Creative engineers

Sir — Darnbrough (*Nature* 18 March, p.192) and Austen (*Nature* 25 March, p.284) both miss, or intentionally obfuscate, my analogy about the evolution of aeroplanes and biological evolution. Both processes lead from the simple to the highly complex. Hoyle and Wickramasinghe, not I, chose the aeroplane simile and implied that evolutionists believe that "higher life forms evolved by chance", and that a gene "might be chosen from 10²⁰ nucleotide sequences of the appropriate length". This implies that large complex proteins appear without any intermediate

Actually, proteins are thought to have evolved by the joining together of short polypeptides, as pointed out by me (Molecules and Evolution, Columbia University Press, pp. 222-229, 1960), and further explained by Rout (Nature 18 March, p.192). Yeas has given striking examples of this process in "periodic" proteins such as collagen and keratin (J. molec. Evol. 2, 17; 1972). Lengthening was probably by duplication and recombination in DNA, followed by an accumulation of point mutations.

Obviously the evolution of aeroplanes, completed in a few years, was a product of the creative genius of engineers. The point was that the Boeing 747 did not suddenly appear on the scene. In contrast, biological evolution took millions of times as long, and was impelled by slow, insensate natural phenomena. Austen says that "without a Creator, atoms and molecules, which He created, are still atoms and molecules". How could atoms and molecules exist without a Creator if He created them?

A thermal history

Sir — Many letters in recent issues of *Nature* show little unanimity about the mechanisms or rate of evolution. There may, however, be agreement that organisms do not adapt to, or evolve for, life in non-existent environments: nor do they retain capacities needed in an environment in which they no longer live.

In the course of their mainly reasonable discussion on the probable thermal history of Earth, while exposed to a steadily increasing rate of inflow of solar energy, Lovelock and Whitfield (Nature 296, 561; 1982) quote the observation that 50°C is the "critical upper limit for most life" as a factor supporting their thesis that the overall temperature never fluctuated greatly from today's values. That particular piece of evidence is not very cogent. Hot environments, such as hot springs and submarine spreading centres, are small and, from an evolutionary and geological standpoint, evanescent. Circumstances do not now exist that favour the evolution of organisms adapted to life at high temperatures, nor the persistence of that ability if it existed earlier.

The fossil record tells us nothing about the thermal preferences of very early organisms.

Biological potentialities should not be underrated. Enzymes vary in thermostability so, if granted several million years of undisturbed occupation of an extensive hot site, there is good reason to expect the emergence of proteins more robust than those with which we are familiar. It is not just a coincidence that the boiling point of water under today's atmospheric pressure is the limit beyond which no organisms are known to be able to live, and that very few organisms can approach that temperature. There would be no advantage in the ability to exceed that temperature - or in many organisms adapting to it. And proteins are not the only conceivable vehicles for quasi-enzyme activity. Had there been a prolonged period when the overall temperature was greater than it is now, there is no reason to assume that organisms adapted to it could not have existed. Recognition of this possibility extends the scope of discussion about the origins of life. N. W. PIRIE

Rothamsted Experimental Station, Harpenden, Herts, UK

Not unilaterally

SIR — Though you published an editorial (*Nature* 1 April, p.380) commenting on the three letters contained in that issue replying to the editorial of 18 February (p.542) criticizing the use of professional reputation to give credibility as it were through the backdoor, to causes like disarmament, you failed to notice the essential sophism of the points in the letters. And as this sophism is of much wider consequence than the matters addressed in these letters, affecting the whole popular movement of opinion on a subject of great importance, it deserves attention and debate.

The error is seen in the tendency to deduce from the articulated description of the horrors of nuclear war, the wrongness of, and hence the desirability to prohibit, nuclear arms. It was not felt by any of your correspondents necessary, beyond showing how awful the results of nuclear war are, to argue that disarmament has any relevance to diminishing the risks of war.

It seems to me that those who in supporting disarmament say that they are primarily concerned to achieve a wider public awareness of the consequences of nuclear war, are in fact advocating response rather than consideration. They imply by arguing how wrong nuclear wars are, that the obvious conclusion is that to prepare for the eventuality of such a war is also wrong. To argue like this is to take advantage of the association of ideas in the mind, but to evade the rational consideration of what causes war.

Although it is not my intention to argue for nuclear weapons, only to point out that the greater salience of an idea does not excuse a failure to demonstrate the validity of an argument, it is important to remember that wars are initiated in the expectation, however misconceived, that winning them is possible. Nuclear weapons as presently shared between the superpowers do not allow such misconceptions, though after unilateral disarmament one fears they could.

J. R. SKOYLES

Propaganda war

SIR — Your leading article of 1 April (p.380) headed "Professional propaganda" complains that professional groups, such as physicians who state that the threat of nuclear war currently presents the most urgent challenge to preventive medicine, do not at the same time offer alternative political and military solutions to the problems of arms control and defence. I suspect that if they were to try to do so you would censure them for making pronouncements on subjects beyond their expertise.

You would, however, be mistaken to presume that those who take the step of joining organizations such as Physicians for Social Responsibility in the United States or the Medical Campaign against Nuclear Weapons in the United Kingdom are politically ignorant. It is because they know enough to be unconvinced by assurances that nuclear weapons are necessary and for the best that they try to bring home to the public and to politicians the dangers of regarding such weapons as acceptable instruments of policy. Similar concerns also stir physicians in other countries, both East and West. At a congress held in Cambridge recently by International Physicians for the Prevention of Nuclear War (an arrogant title, perhaps, but not inaccurate) some two hundred eminent participants from 31 countries were unanimous in concluding that nuclear war - whether intended or resulting from tragic accident - would be catastrophic for any countries involved and might have dire consequences for humankind, that the medical services could have only a marginal effect in mitigating the suffering of immediate survivors, and that it was a continuing duty to bring this home to the public and to politicians in their own countries.

The congress agreed some carefully prepared statements, among them letters to President Reagan and Chairman Brezhnev which included the following outright recommendations for political action:

"We believe that action must be taken now to prevent nuclear war and to relieve the consequences of the arms race. We urge that as a first step, the nuclear powers cease all further production, testing, and deployment of nuclear weapons and their delivery systems. This should be accompanied by mutually acceptable methods of verification. We further urge that all nuclear powers unequivocally renounce the use of such weapons, and agree to prevent their introduction into any conflict. We advocate effective bilateral and multilateral negotiations on the limitation, reduction, and ultimate elimination of nuclear weapons.

We are aware that negotiations have been in progress for many years with essentially no apparent effect on the arms race. While we welcome any initiative by either side to reduce its stock of nuclear weapons, we recognize that they are likely to be eliminated only by negotiation. We must again urge that such negotiations be pursued seriously and continuously until they succeed."

Britain's resources of coal and spent uranium fuel

Robert Olby*

THE United Kingdom is often described as a favoured nation in an increasingly energy-hungry world - possessing riches of coal, and also North Sea oil and gas and an abundance of spent fuel from nuclear reactors. Before the OPEC oil price rise of 1973 it was generally accepted that dependence on coal should continue to decline in favour of oil and nuclear power. The imposition of a fuel tax on oil in 1961 marked an attempt to slow down the rate of oil substitution, but nevertheless between 1959 and 1973 oil consumption more than doubled, and by 1973, 3 per cent of total primary energy was supplied by nuclear power. The action of OPEC not only strengthened the argument for nuclear power based on its contribution to national security but within the National Coal Board it brought to the fore the already active concern to reassess the future of

In the board's Plan for Coal (1974), investment of £1,400 million over the following decade was proposed, £8 million, of which was to be spent on an intensified programme of exploration to decide on the best sites for future development. Three years later, this expansionist mood became apparent to all with the announcement of the board's revised estimates of the United Kingdom's "physically recoverable" reserves. To a British Association audience the then-chief geologist to the board, A. Michael Clarke, declared that economics and a lack of sufficient physically recoverable reserves of coal were not the sole determinants of the choice between coal and nuclear future bulk energy supplies for Britain and Europe. Just because the era of cheap oil had taken an unnecessary slice from the life of UK coal reserves, it was not the case that in the long-term we lacked adequate reserves. To go nuclear, he declared, was not therefore inevitable.

The United Kingdom's reserves, which the World Energy Conference Survey of Energy Resources for the reference year 1975 (published 1977) had shown as 3.887×10^9 tonnes, were now claimed by the board to be 45×10^9 tonnes. Small wonder that this apparent dramatic change caused adverse comment from the Institution of Geological Sciences (IGS), letters in The Times and a tart editorial in Nature.

In 1975 Sir John Hill, chairman of the Atomic Energy Authority, drew attention to the potential energy source available in spent uranium fuel. With the fast reactor, he claimed, Britain's spent fuel could yield

*The University of Leeds Department of Philosophy, Leeds LS2 9JT, UK.

as much as 50×10^9 tonnes of coal, more, he declared than Britain's total coal reserves which, according to the National Coal Board in 1969 were about 20×10^9 tonnes. In 1976 Sir John's colleague T.N. Marsham gave the more conservative coal equivalent of stored spent fuel as 20×10^9 tonnes, which Sir John later doubled to 40×10^9 tonnes a year. Between these two values came the Coal Board's new estimate of Britain's coal reserves at a little more than twice T.N. Marsham's figure.

rate of expansion of coal extraction of the first half of that century (800 per cent). Such a drain on the country's "life-blood" would exhaust its resources by AD 2034. On the other hand, if, as Edward Hull believed, the coal industry would be incapable of raising more than 100 million tons per annum, the nation still had eight centuries of supplies. Meanwhile he looked to science to show how we could win energy from "the light and heat that is everywhere around us". Appealing to God's provi-

During the 1970s estimates of the United Kingdom's reserves of coal and spent fuel from nuclear reactors, provided by the National Coal Board and Atomic Energy Authority respectively, have tended to steadily increase. It is tempting to infer a connection between these estimates and the efforts of the NCB and AEA to promote their claims on government finance, by each predicting as long-lived a future secure energy source as its rival. This article follows the history of the various estimates and attempts to assess their credibility.

Dwindling resource

Although the long-term future of coal as the United Kingdom's chief energy source was a matter for concern after the Second World War, the subject had long been debated. In 1789 John Williams discussed the "limited quantity of coal in Britain" in his book Natural History of the Mineral Kingdom, and in the 1810 edition edited by James Miller, Macnab's 1792 estimate of 360 years' supply was given. This figure related only to the coalfields of Northumberland and Durham and the extraction rates of that period. In the nineteenth century the Oxford geologist, William Buckland, urged upon the parliamentary committees of 1830 and 1835 the need to conserve coal. In 1830 the old sea-coal tax had been abolished, but twelve years later Sir Robert Peel put a tariff on all exported coal.

The subject of coal resources came before Parliament once again when the Commercial Treaty with France was debated in 1860. According to Article 11, no duty was to be levied upon coal exported to France and other nations with whom the United Kingdom was at peace. It was the discussion of this treaty which caused Edward Hull, member of the Geological Survey, to write The Coalfields of Britain (1860) in which he took a sanguine view. Introducing the mining limit of a depth of 4,000 feet he reckoned England and Wales had just under 59×109 tons, enough for about a thousand years. In the second edition of 1862 Hull included the Scottish coalfields which raised his estimate to 79.8×109 tons. Hull recoiled from the implications of continuing indefinitely the dential character he assured his readers: "nor can we suppose that any part of the Creator's universe has been regulated on so short-sighted a plan, that it shall become disorganized because some of the elements necessary to its economy have failed".

The optimism of Edward Hull was matched by the stern realism of the economist and statistician, W. Stanley Jevons. In his celebrated work, The Coal Ouestion (1865) he calculated the duration of British coal on the basis of Hull's estimate of reserves and the extrapolation into the future of the historic trend in coal consumption, which had been 3.4% per annum over the decade 1851-61. His conclusion was that: "Rather more than a century of our present progress would exhaust our mines to the depth of 4,000 feet . . . " Jevons was widely misunderstood as predicting exhaustion around the year 1975, whereas he was really trying to show that the nation's industrial expansion could not continue for long at the rate then current. Whilst there was still plentiful cheap coal attempts should be made to reduce the national debt, introduce a general system of education, and impose a far more general restriction on child labour. Such tasks would be more difficult to achieve when other countries reached and surpassed the output of Britain's mines, becoming more competitive in world markets (by 1967 US pithead prices were half those of Britain). Although Jevons foresaw this situation he could not, as a free-trader, recommend the imposition of an export tariff on coal. Therefore it was clear to him that the cost of coal extraction was a decisive factor in determining the proportion of Britain's total coal resources which would be extracted. In the future we might, indeed, be able to mine coal at greater depths than at present, but only if the price was competitive in world markets. There was no question of the physical exhaustion of our coalfields—"though we may some day have to pay dear for fuel; it will never be positively wanting", he explained in the second edition of *The Coal Question*. Here Jevons was expressing what later became a major feature of the distinction between reserves and resources, the history of which is recounted below.

Jevons drove his point home by a demonstration of the unique character of coal. In a remarkable chapter on subtitutes in the third edition of his book (1906), he discounted sunlight, peat, hot springs, water and wind power, the tides. petroleum, hydroelectricity and hydrogen produced by the electrolysis of water. He found it absurd to picture the 7,308 horses or 1,000 large windmills which would be required to power a modern factory like the great Dowlais ironworks, and he pointed to the fallacy of considering electricity as a source of self-creating power. The chief targets of this critique were the optimists, Dionysius Lardner, Charles Babbage and Edward Hull.

Sir John Herschel applauded Jevons. "Such a work as yours", he wrote, "has long been wanted to dissipate completely the delusion which so large a majority of our countrymen labour under, of the 'inexhaustibility of our mineral resources' etc. and the 'probability amounting to certainty' that science will ere long put us in possession of a substitute for coal . . . after this let no man plead ignorance and say 'who would have thought it'." Herschel went on to describe his favourite notion of using the tides by running pipes under the sea to a distance of 1,000 feet around 1,570 miles of coastline from Berwick-on-Tweed to the Solway Firth. With a 6-foot tidal fluctuation he reckoned this vast construction would supply only one million tons of coal equivalent — one fifth of London's annual consumption or enough to keep ten Great Easterns constantly under steam.

By the summer of 1866, Jevons had become a newspaper celebrity. Gladstone wrote to him, J.S. Mill quoted him and Queen Victoria appointed a Royal Commission on coal chaired by the Duke of Argyll. In its report five years later, this commission estimated the amount of coal which "may reasonably be expected to be available for use" as 90.2×10^9 tons in ascertained coalfields, plus a possible 56.3×10^9 tons elsewhere. The resulting total recoverable resource figure of $\sim 146 \times 10^9$ tons within a depth of 4,000 feet appears to have been accepted.

The commissioners were sceptical of making projections of future demand based on historic trends; they doubted that Britain's coal would ever be absolutely exhausted, but the country would lose its

advantageous position in regard to coal supplies, coal imports would become the rule rather than the exception. Ominously the report concluded with the sentence: "But it may well be doubted whether the manufacturing supremacy of this kingdom can be maintained after the importation of coal has become a necessity." These views were not substantially revised by the Royal Commission of 1901, nor by anyone else.

Like their 1871 predecessors, the 1901 commissioners misunderstood Jevons. They arrived at an estimate of total available coal to 4,000 feet of nearly 142×10^9 tons, 40.7×10^9 tons being in "unproved" coalfields. The approximate agreement between the two commissions' estimates, despite the quantity of coal extracted in the interval, was due in Jevons' son, Herbert's, opinion "to the well known law that a number of unbiassed errors tend to cancel one another". Nevertheless it consolidated a growing consensus that Britain had at least 140 × 109 tons of which the proportion in "proved" coalfields was increasing due to continued exploration. Conversely, the consensus was developing that as more of the best and most accessible coal was removed, the remainder would be increasingly difficult and expensive to mine. Therefore, the 1901 commission declared, the rate of increase of extraction, "will soon be checked by natural causes" so that there was "no present necessity to restrict artificially the export of coal in order to conserve it for our home supply".

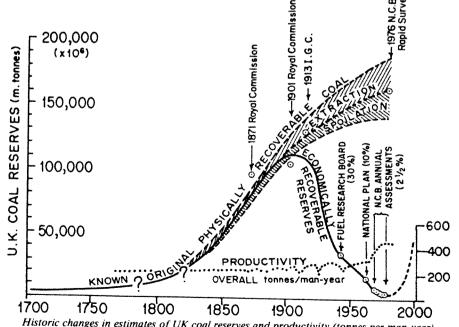

In the inter-war period, the coal industry laboured under many difficulties, the chief of which was falling demand. By the time of nationalization in 1947 it was in a parlous state, having suffered from many years of financial stringency and lack of investment. Despite extensive mecha-

nization output had not grown as it had in continental mines. This was chiefly due to the winding and undulating character of the underground lay-outs ("in-seam mining") in Britain in contrast to the straight roads which were driven through the strata on the continent ("horizon mining"). The latter layout was easier to mechanize throughout. In Britain the work of the coal-filler at the end of the conveyor belt remained unmechanized and constituted the bottle neck in the system until the 1960s.

Although Britain did not suffer so acutely after the Second World War as other European countries from coal shortages, demand was depressed by the system of allocation to consumers and there were frequent electricity cuts. Even allowing for the growth of the oil industry with Marshall Aid a long-term reorganization of the coal industry would be required to expand production. Such anticipated expansion did continue until 1958 when the threat of cheap oil began to bite into coal's traditional markets confounding the prophets of its future demand.

In such difficult circumstances mines were being closed at a rate of 40 a year, and the economically workable reserves were written off (depleted) at an alarming rate. The result is seen in the figure below.

The value of 3.87×10^9 tonnes appeared in the 1974 World Energy Conference Survey of Energy Resources alongside a figure for total coal reserves of 99×10^9 tonnes and almost 163×10^9 tonnes for total resources. It did not escape the notice of the conference report that the United Kingdom's recovery percentage was thus only 4 per cent in contrast to West Germany's 40 per cent. On his return from

Historic changes in estimates of UK coal reserves and productivity (tonnes per man-year). Adapted from A.M. Clarke in Australia's Mineral Sources (eds G.M. Philip & K.L. Williams, Sidney, 1978).

the conference Leslie Grainger, the National Coal Board's Member for Science, pointed out the absurdity of these data to the board.

A hint of what had happened can be found in the World Energy Conference Survey for reference year 1975. Although total reserves were now nearly 101×10^9 tonnes, economically recoverable reserves were still only 3.887 × 109 tonnes. From a footnote we learn that this figure concerned reserves at existing collieries and opencast sites (what are usually described as "operating reserves"). A second footnote tells us that the National Coal Board's "alternative" estimate for economically recoverable reserves (not restricted to those with access from existing mines and by local marginal costs) was 45×10^9 tonnes.

Resource terminology

Was this confusion merely a product of the semantics of resource estimates or of some deeper issues? Clearly there is still not a consensus over the former if only because different resources tend to be suited to different terminological rules and the needs of the smaller commercial mining companies are not the same as those of a nationalized industry. The roots of a precise terminology can be seen in Herbert Hoover's little classic, The Principles of Mining (1909), where the tripartite division of mineral ores into proved, probable and prospective was recommended. Four years later the staff of the Canadian Geological Survey, in their task of assessing world coal resources for the twelfth International Geological Congress, asked for returns to be classified into two groups (above and below 4,000 foot depth) and these to be subdivided into actual, probable and possible. These terms, or their equivalents, were used by mining engineers and mining geologists in the preparation of expert advise on the likely profitability of mining ventures. They expressed the level of confidence to be placed on the extent and availability of the resources in the mine, and were intended to protect the investor from exposure to fraudulent claims made on behalf of unsound commercial ventures. Therefore they referred to existing technical and economic conditions.

During the Second World War the United States government, concerned about their mineral resources, held Senate hearings on the subject at which the Bureau of Mines and the Geological Survey (USBM/USGS) proposed a new tripartite definition of reserves as measured, indicated, and inferred, each division representing defined levels of reliability, the highest being the ± 20 per cent of measured reserves. The long-term needs of such national assessments led S.G. Lasky in 1949 to make an important distinction between reserves and resources, two terms hitherto used interchangeably. Whereas reserves (measured, indicated and inferred)

were known to exist and had "aspects of usability within a practical limit of time and within a specified set of economic and technologic conditions", resources comprised "all materials in the ground, discovered or undiscovered, usable at present or not, . . . considered within the context of all factors . . . that may influence its conversion into a "reserve", and . . . that enter into prediction or opinion as to possible future usability". This distinction was recognized in Blondel and Lasky's 1956 equation:

Resources = Reserves

- + Marginal resources
- + Submarginal resources
- + Latent resources

It has become increasingly recognized internationally, and has influenced the World Energy Conference classification whose 1974 Survey definitions were:

- Total resources: "The total quantities available in the earth that may be successfully exploited and used by man within the foreseeable future."
- Total known reserves-in-place: "The corresponding fraction of resources that have been carefully measured and assessed as being exploitable in a particular nation or region under present local economic conditions using available technology."
- Recoverable reserves: "That fraction of reserves-in-place that can be recovered under the above economic and technical limits."
- Additional resources: "All other classifications with a lower degree of geologic certainty as to their existence than those indicated as known."

Of this last category the 1980 Survey remarked that they:

embrace all resources, in addition to proved reserves, that are of at least foreseeable economic interest. The estimates provided for additional resources reflect, if not certainty about the existence of the entire quantities reported, at least a reasonable level of confidence. Resources whose existence is entirely speculative are not included.

What, then, is the meaning to be attached to the United Kingdom's 1977 figures of (in tonnes):

Total reserves	100×10^{9}
Economically recoverable	45
reserves	
Additional resources	45
Total resources	190

The National Coal Board maintains that within 1.2 km depth and in seams over 60 cm thick there are about 190×10^9 tonnes of coal, of which some 100×10^9 tonnes are well ascertained but no figure has been given for the confidence level. These estimates are in line with the general trend of the Royal Commissions of 1871 and 1901. The figure of 45×10^9 tonnes for economically recoverable reserves shows the recognition of the fact that recovery of what is known to be in the ground has fallen from the nineteenth-century level of between 70 and 80 per cent to about 50 per

cent. This fall, due to both economic factors and to mechanization, could in Clarke's opinion be reversed under high oil prices and a vigorous programme of coal exploration. Over the next decade K. Moses thought the figure for economically recoverable reserves might well rise to 50 or even 60×10^9 tonnes. Clarke suggested the possibility of returning to the older recovery percentages which would push the figure up to 90×10^9 tonnes. Before the oil price rise of 1973, George Armstrong, then chief geologist to the National Coal Board assessed the current recovery of reserves at about 25 per cent, but he clearly anticipated a major change in the industry given increased investment. With capital, he explained, "access could be made to the best seams in the vast extentions of our existing coalfields", and we should see "for the first time since the latter part of the nineteenth century . . . an increase in the reserves of coal in Britain which can be considered as economically workable". He never denied the 200×10^9 tonnes total UK resources but considered this figure of "only academic interest" and "grossly erroneous as an estimate of economically workable reserves". It was right that under stricter rules of resource estimation the old UK figures, like the early American ones, should have been reduced. It was not that some of this coal had never existed, or had vanished since 1900, but that the onus was put on the coal industry and the nation to support the exploratory research and technical development needed to bring more and more of the resources into the reserves, and thus afford a clearer picture of the future potential of our coalfields.

Nevertheless, it should be stated that there is not yet a consensus between geologists within and without the coal industry as to how much of the coal in the UK's abandoned fields remain accessible for future extraction.

Towards atomic power

The recognition of the industrial advantage to be reaped by the nation which leads the world in the exploitation of a new source of power lay behind the public and governmental enthusiasm for exploiting the atom. Radioactivity was considered as a possible novel source of power long ago in the Times Literary Supplement for 17 July 1903. Radium was considered amongst those "gigantic possibilities, which are not probabilities at all yet . . . ". Frederick Soddy, who had "ghosted" the article, pictured how much energy radium would yield if its rate of disintegration could be speeded up. Rutherford, the article reported, "has calculated from his own experiments and those of Curie that the energy stored up in one gramme of radium is sufficient to raise 500 tons a mile high. An ounce would therefore suffice to drive a 50 horsepower motor car at the rate of 30 miles per hour round the world". If it could be achieved with radium if could be achieved with uranium and thorium. "Our

fathers busied themselves with speculating what would become of us when the world's supply of coal was exhausted. A single step of science is needed for that problem to be answered in a manner beyond the dreams even of the scientific novelist."

We all know that these prophetic words were fulfilled (for uranium not radium) when in 1939 Lise Meitner and Otto Frisch interpreted the experimental results of nuclear fission; and Halban, Joliot and Kowarski, Fermi and others discussed the possibility that it might be accompanied by a chain reaction. That year was not only the annus mirabilis of nuclear fission, it also marked the first attempt to calculate the potential electricity output of a power station run from a "uranium boiler". S. Flügge calculated in Die Naturwissenschaften that complete fission of one cubic metre of uranium oxide powder would yield 7×10^{10} kWh of electricity, sufficient to replace the entire output of Germany's power stations running on middle-German brown coal for 11 years.

Comparisons such as Flügge's have been made repeatedly since 1939 in order to give some conception of the contrast in the concentration of energy in fissionable fuels as compared with fossil fuels. Hitherto the largest yield from a nuclear transformation had been the 22.2 MeV from the conversion of lithium (6Li) into alpha particles (4He). But when M.C. Henderson measured the energy yield from uranium in 1939 it was a staggering 175 meV (theoretical value, 198 MeV). (The beta decay of radioactive fission products subsequent to fission of 235U is 21 MeV, and has to be subtracted from the 198 MeV.) The table below illustrates the million-fold increase in yield per atom when we go from combustion to fission.

Theoretical energy yields per atom

12C	Combusion	4.17 ev		
²²⁶ Ra	Fission	4.79 MeV		
235U	Fission	198 MeV		

When we compare uranium and carbon weight for weight the ratio is approximately 3 million to one. But H.D. Smyth in his report on the Manhattan project considered what the fission/combustion ratio would be if by fission all the matter of the atom was converted into energy. The equation relating matter and energy $(e = mC^2)$, he wrote,

... shows that one kilogram (2.2 lbs) of matter, if converted entirely into energy, would give 25 billion Kwh of energy. This is equal to the energy that would be generated by the total electric power industry in the United States (as of 1939) running for approximately two months. Compare this fantastic figure with the 85 Kwh of heat energy which may be produced by burning an equal amount of coal.

Smyth knew then, as we know now, that less than 0.1 per cent of the matter in uranium can be converted into energy by fission (to be precise it is 0.091 per cent). His calculation showing a ratio of 3×10^9

to one was therefore knowingly a thousand-fold exaggeration. He also knew what Flügge did not know, namely that only 1 in 139 (usually stated as 1 in 140) of the atoms in uranium is readily fissionable with slow neutrons, that is, those of the isotope ²³⁵U.

As later experience showed, the utilization of uranium by Britain's Magnox reactors is about 0.5 per cent (of which ²³⁵U contributes about 0.35 per cent and the rest comes from the isotopes of plutonium and other elements). Taking a very high grade uranium ore with 1% uranium content, one fifth of which is recovered in extraction, and comparing it with a second-grade, bituminous coal (50% carbon) and some 30% of stone chips and dust our 'from the ground' ratio for Magnox reactors would be:

$$\frac{3 \times 10^6}{100 \times 200} \times \frac{1}{5} \times \frac{100}{35} = 86.1$$

Research carried out in the United States during the Second World War made uranium look much more attractive than the 21,000:1 ratio suggested, for the elements heavier than uranium, elements 93 and 94 in the Periodic Table, were discovered as products of neutron capture by the abundant isotope of uranium, ²³⁸U. By 1941, Glenn Seaborg and co-workers had isolated element 94 and called it plutonium, ²³⁹Pu. As expected from theoretical considerations it proved fissile together with ²⁴⁰Pu and ²⁴¹Pu by both thermal and fast neutrons.

Estimates of world uranium supplies won a new significance in December 1951 when the US experimental breeder reactor (EBR 1) yielded electricity to the grid and it had been shown meanwhile that the number of atoms of the abundant ²³⁸U converted to fissile ²³⁹Pu exceeded the number of ²³⁵U atoms fissioned. That meant that more fuel was 'bred' than was consumed.

The principle of the breeder reactor having been experimentally established. energy forecasters waxed confident about a world energy future based on uranium. Palmer Cosslet Putnam in his report to the US Atomic Energy Commission in 1953 included all low-grade sources of uranium in his calculation of recoverable world reserves at 25 million tonnes, with an energy yield of 1,716Q, one third of which - 575Q — it would be economical to 'burn'. As he was contracted by the commission to estimate the maximum possible contribution which nuclear power could make, it is hardly surprising that this estimate of uranium reserves was wildly exaggerated. Today figures in the range 6.6 to 14.5 million tons have been dismissed as misleadingly fanciful. Total world reserves are still put at less than 2 million tons, plus additional resources of little above 1.5 million tons. When Hans Thirring reworked Putnam's uranium estimates in 1958 he neglected or rejected the one third utilization which Putnam made to allow

for losses during recycling of the fuel in the breeder, with the result that Thirring's value for uranium reserves was 2,000Q. "The date of depletion of the energy capital of our Earth", he concluded in Energy for Man, "is therefore prolonged by at least a millenium . . Thus the consequence of Hahn's great discovery will free us from the fear that our energy resources will run out within quite a short period of history."

US coal resources

A more surprising aspect of Putnam's report was his reworking of the estimates of US coal resources. To the 1944 figure of $3,100\times10^9$ tonnes (total resources) he applied a series of correction factors which reduced it by nine tenths. As Schurr and Netschert have well said Putnam's resulting 3.1Q's worth of recoverable US coal reserves "is based on limiting criteria that have no consistent basis; some of them are wholly arbitrary and some of them have no relation to coal actually in stock".

Nuclear scientists have to their credit that they have in the past cautioned against the acceptance of wildly enthusiastic claims for nuclear power. Such euphoric remarks included the "pill-in-a-pail" suggestion made in the US Congress in 1946. All you needed to heat your house for a year, according to this idea, was a small pill of uranium in a pail of water. Other calculations suggested that a piece of uranium the size of an egg would propel the Oueen Mary from New York to Europe and back, whilst other pundits claimed that one the size of a pea placed under the doorstep would suffice to heat a house for its entire lifetime.

At the end of the Second World War, experience with the Hanford reactors had shown that very little of the 0.7 per cent ²³⁵U in the fuel was 'burnt' before 'poisoning' seriously reduced fission. This led Oppenheimer in 1947 to advise that it did

not appear hopeful to use natural uranium directly as an adequate source of fuel for atomic power. The reactivity of systems based on natural uranium is low; even the fraction of ²³⁵U which can be consumed without replenishing the fuel is small. Because of this the raw material requirements, if such reactors are to play an important part in power economy, are economically prohibitive. It is true that one could re-enrich this natural fuel, but the power expenditure involved in such isotope separation by any present methods makes this likewise prohibitive.

Although the General Advisory Committee to the Atomic Energy Commission discussed drafts of Oppenheimer's memorandum, it was not published for fear of undermining congressional support for the commission. Oppenheimer's ground for pessimism over natural uranium reactors has, as we know, proved exaggerated. Britain's Magnox reactors do 'burn up' some 0.5 per cent of the entire fuel since they fission about half

the ²³⁵U and some of the plutonium they produce. Nevertheless reactors of this type are no longer built, precisely because they use so little of the fuel.

Considerable caution was also expressed at the first nuclear power session of the World Power Conference when the subject was included in this organization's Fuel Economy Conference at The Hague in 1947. Charles Thomas's calculation of the cost of nuclear electricity (nuclear 0.8 cents per Kwh, coal 0.65 cents) for the UN Atomic Energy Commission in 1946 was attacked by Con. Edison's research engineer, Ward F. Davidson and others. Both Sir John Cockcroft and L. Kowarski were cautious, the latter being decidedly caustic about the fast reactor. The tone was again cautious at the full session of the World Power Conference in 1951. Cockcroft said it was "like gazing into the crystal ball to ask us at this stage what operating and capital costs are going to be". At the Atoms for Peace Conference of 1955 he was looking to this "second decade" (the 1970s) for the uranium/coal ratio to be raised by the breeder principle to at least a million to one.

It was in 1951 that work on the fast reactor had begun in the United Kingdom, stimulated by concern over uranium supplies. Eleven years later, the Dounreay fast reactor (DFR) began generating electricity. This 60 MW(t) station was fueled with uranium, 75 per cent enriched ²³⁵U, not plutonium. It was run on full power for five years before being treated as a test bed for plutonium fuels. It has been succeeded by the prototype fast reactor (PFR) using mixed oxide fuel. By 1973 construction was completed and the following year saw operation at low power.

It is surely no accident that the potential world role of nuclear energy was being stressed in the United Kingdom from 1973 onwards based upon the promise of the fast reactor. Its high fuel utilization, claimed Sir John Hill in the magazine Atom, "will enable the vast reserves of very low-grade uranium to be utilized without significantly increasing the overall cost of electricity". World reserves of coal, he admitted, were enormous, but "we are consuming the most accessible and most convenient fuels (gas and oil) fastest and we are depleting most rapidly those reserves which are most conveniently situated geographically, economically and politically". Coal, though abundant, was expensive to mine and transport. Moreover the electricity industry needed flexibility to cope with shortages such as strikes and embargoes could create. Though improvements in UK coal production were impressive, the industry remained in Sir John Hill's words "essentially a labour intensive industry despite increasing use of machinery and, if the men employed are to maintain a standard of living compatible with the task they are being asked to undertake, the labour costs of the industry will rise and this must be reflected in the cost". The

context of these words was provided by the coal price rise of 40 per cent over eighteen months in 1969-70 and the picketing of power stations by mineworkers in 1972. More was to follow — the 140 per cent price rise of coal in 1975, the 400 per cent price rise of oil in 1973-74 and the miners' strike of 1974 which involved a four-month dispute in the industry.

Conclusion

Statistics on fuel reserves do not constitute cold hard facts, they are judgements about the probable outcome of a series of events in space and time. One might even claim tha they do not so much form government policy as result from such policy. Since the introduction of oil-fired power stations in the 1950s the policy of building a multi-fuel base to electricity generation with nuclear base-load has been followed by both political parties. Whereas governments have in the past given some protection to coal against oil there has been from 1955 onwards a consistent policy of favouring nuclear power, a policy shared by the Central Electricity Generating Board whose aim it is to increase dependence upon nuclear-generated electricity for base load, and thus to diminish the impact of higher coal prices and the threat posed by the withdrawal of labour in the coal industry. When the all-party Commons Committee on Energy delivered its report in February 1981, a Daily Telegraph editorial described the recommended "cut-back in nuclear power station construction" as "naive, petty-minded, and ill-informed". The editorial continued:

It is no doubt bad luck for its authors that the report appeared just as an indefinite national coal strike was threatened. But we, on the other hand, should be thankful for the timing. It enables us to see how absurd it would be not to invest massively in nuclear power at a time when coal supplies are under constant threat, and, more important still, when the Russians are reaching out greedy claws towards the Middle East oil wells.

Clearly the formulation of energy policy is a highly political process. The decisions reached can affect the estimates of reserves themselves. Investment in machinery, prospecting, methods of combustion and of fission, all influence what proportion of the total resource may be considered as economically extractable reserves. Thus fluidized-bed-combustion can be achieved profitably with low grade coal of ash content up to 55 per cent instead of the maximum 30 per cent for conventional combustion, thus bringing high-ash coal deposits into the reserves. Similarly highsulphur coals whose combustion causes acid rain can be burnt without liberation of sulphur dioxide in the fluidized bed. Uranium reserves, which at present are trivial by comparison with coal, are increased in terms of their energy yield some sixty-fold with the fast reactor. This, in turn, will allow lower-grade ores to be brought from the resource category and FOR an excellent critical discussion of resource nomenclature the reader is referred to G. B. Fettweiss, World Coal Resources: Methods of Assessment and Resouts (Elsevier, Amsterdam, 1979). Also invaluable are: The Royal Society's submission to the Commission on Energy and the Environment, Environmental Aspects of Increased Coal Usage in the U.K. (February 1980) and the WATT Committee on Energy, Assessment of Energy Resources, Committee Report 9 (1981) and the report of the Commission on Energy and the Environment (1982). The proceedings of the November 1981 British Nuclear Energy Society conference on the fast reactor finel cycle should be published soon. There the "reasonably assured resources" of uranium are given as 2.6 million tonnes.

added to the economically exploitable reserves. There is a sense, then, in which, as Clarke has remarked, an investment decision which significantly favours one energy industry at the expense of the others, is likely to be self-fulfilling, and may thus prove to have been economically and financially correct.

The claimed potentials of both coal and spent uranium fuel reserves raise sensitive issues — fears of increased seismic activity. water table changes and water contamination, in the case of coal mining; concerns about reprocessing and long-term storage, and doubts about the commercial performance of the fast reactor, in the case of spent uranium fuel. If the Coal Board's estimate of 45 × 109 tonnes looks like a 'giant extrapolation' to quote a Nature editorial, how much better are the claims made on behalf of spent uranium fuel? True it has not to be mined, but it will have to be reprocessed many times before even half its energy content has been liberated.

This analysis of energy resource claims does not suggest intentional rivalry by the Atomic Energy Authority and the National Coal Board. Their presentation about the same time was fortuitous. That they both represent responses at the political level in the campaign for government support seems evident. Also clear from this analysis is the fact that the modern distinction between resources and reserves, though dating from 1949, is still in the process of winning general acceptance. Reluctance to adopt it might well be due not only to tradition but also to the tendency which strict definitions of economic reserves have to belittle the long-term potential of an industry's resources. If decision-makers have some appreciation of the factors involved in the process of converting resources into reserves then the application of this fundamental distinction of nomenclature will be more consistently adopted.

I acknowledge the assistance of Mr A. Michael Clarke, Dr Leslie Grainger and Professor E. H. Francis; Mr Keith Bowes kindly commented on an earlier draft of the section of the paper given to nuclear energy. The extract from Oppenheimer's memorandum to the AEC Advisory Committee is cited with the permission of the US Department of Energy.

NEWS AND VIEWS

Not quite full circle? — non-racemic amino acids in the Murchison meteorite

from C.T. Pillinger

In this issue of Nature (p.837), Michael H. Engel and Bartholomew Nagy report finding partially racemized glumatic acid. aspartic acid, proline, leucine and alanine in the Murchison meteorite. They believe the amino acids to be indigenous to the sample, even though full racemization is usually accepted as the indicator that such compounds were present before the meteorite's arrival on Earth. Nevertheless. the authors present a good case and, to their credit, make no attempt to invoke extra-terrestrial biology as an obvious and sensational interpretation of the results. Engel and Nagy only speculate that some type of stereoselective synthetic or decomposition reactions could have taken place on the meteorite's parent body. Less responsible scientists will not be so cautious or await proof that some unusual form of terrestrial contamination was not responsible for the differences between the latest results and samples previously studied.

This publication could be said (unkindly by some) to set back the study of carbonaceous substances in meteorites by some twenty years since it was in 1961 that Nagy, writing with W.G. Meinschein and D.J. Hennessy1, presented the results that sparked off a decade of controversy. Using organic mass spectrometric techniques which were just finding widespread use in the petroleum industry, the group had discovered aliphatic and aromatic hydrocarbons in the Orgeuil meteorite. At the time such precise chemical structures were considered as 'chemical fossils' or 'biological markers' when found in ancient sedimentary rocks and petroleums. The analogy seemed simple - carbonaceous chondrites must be the extra-terrestrial counterparts of such materials. In voicing this conclusion, Nagy and his co-workers were following the suspicions of previous generations who, beginning with Berzelius², questioned whether the results of meteorite analyses were providing "a hint concerning the presence of organic structures in other planetary bodies"

After 1961, a period of vigorous activity ensued, during which many of the classes of compounds common in the Earth's sedimentary regime were located in one or other of a few known carbonaceous chondrites (see ref.3 for a review). Similarly,

C.T. Pillinger is in the Department of Earth Sciences, University of Cambridge, Cambridge CB2 3EQ.

electron microscopic searches for microfossils were initiated and became the subject of acrimonious debate - another controversial area that has just been resurrected (H.D. Pflug, Public Lecture, Cardiff, 26 November 1981).

All the investigations faced the problem that the samples being studied were not fresh; carbonaceous chondrites are extremely porous and friable and some of the most interesting over 100 years old. Who could know what dubious fate had befallen them at the hands of loving collectors and curators? Then, in 1969, the necessary samples were provided. First, on 8 February, a large shower of material landed near Pueblito de Allende, Mexico, almost on the doorstep of the expectant Lunar Receiving Laboratory at Houston. Within possibly hours and certainly two or three days, large samples were being carefully stored free from contamination. Yet despite these precautions, appreciable quantities (1 p.p.m.) of 'biological' hydrocarbon and fatty acids were found4 in exterior, but not interior, portions of the meteorite, presumably having accrued during the brief passage through the atmosphere and sojourn on the ground. The lesson was salutary.

But Allende was still not the right meteorite: that arrived later the same year near Murchison, Victoria, Australia. Some of the first results reported for the sample concerned amino acid analyses5. By this time gas chromatographic techniques had progressed considerably and it was possible to separate amino acid enantiomers, appropriately converted to diastereomeric derivatives, on optically inactive stationary phases. Kvenvolden et al. found that the asymmetric amino acids in Murchison were fully racemized, that is, equimolar mixtures of the possible isomeric forms. Since amino acids from active biological systems are specifically laevo-rotatory or L-form, the authors were able to exclude the possibility that terrestrial organisms had contaminated their sample. Moreover, the distribution of structures was different from that encountered in biological proteins. The fact that simple molecules such as glycine, a-amino butyric acid and α-alanine were most prolific convinced Kvenvolden et al. that they had encountered extraterrestrial amino acids of abiogenic origin.

The Engel and Nagy paper (see p.837) is almost entirely given over to arguments supporting their conclusion that the par-

tially racemized amino acids they find in Murchison are indigenous to the sample. Briefly, these include the observation that the least racemized acids are the most difficult to extract, and the absence or only trace occurrence of common protein amino acids tyrosine, methionine and phenylalanine and the fingerprint indicators serine and threonine. Appropriate controls are offered to demonstrate that the extraction process did not cause the partial racemization or obliterate the evidence of terrestrial contamination. A selected ionmonitoring technique is used to demonstrate that the apparent inbalance in stereoisomer concentrations is not due to some unsuspected co-eluting contaminant. Finally, corroboration of the results was solicited by circulating the samples to colleagues working in the same research area. One less than satisfactory statement is the suggestion that the present study "may not contradict previous reports, because a large interior sample was analysed". Surely small samples would be expected to show inhomogeneities in distribution, not the

Further examinations of amino acids from clean carbonaceous meteorites would indeed be beneficial. What is needed is an absolute indigeneity criterion, independent of stereoisomerism. Not long ago⁶, it was recognized that the total amino acids isolated from Murchison were isotopically very distinct from their terrestrial counterparts and polar extractables from several carbonaceous chondrites are enriched in deuterium7. Perhaps the intramolecular isotopic composition of individual enantiomers will provide the answer; not an easy measurement to perform but feasible in the long term.

Oh that Engel and Nagy had found excesses of p-amino acids, then one could accept the data or suggest some grudgebearing hoaxer had spiked the sample! But that would be even more difficult to explain. After all, we are looking for a source of abiogenically produced L-amino acids to set biochemistry on its discriminatory way.

Mutualistic interactions among species

from Robert M. May

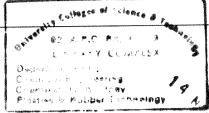

MUTUALISTIC interactions between species have traditionally received significantly less attention from ecologists than have competitive and predator-prey interactions. Recent years have, however, seen growing awareness of this fact, and, in my opinion, empirical and theoretical studies of mutualistic associations are likely to be one of the growth industries of the 1980s. This was one of the themes of the Special Symposium on "Mutualism: New Ecological Theories" held under the auspices of the AAAS at its Annual General Meeting in Washington, DC, in early January.

In opening the Symposium, Boucher observed that mutualism has been cast in the role of the invisible Holy Ghost among the trio of basic types of interaction (see also the review by Boucher et al.1). In elementary biology texts, the contending elaims of competitive and of predatorprey relationships as regulators of population density are usually discussed, while mutualism is dismissed descriptively with some colourful pictures and engaging anecdotes. Most of the current generation of ecology texts compound this disparity: competition and predator-prey typically each have one or more chapters to themselves, replete with discussions of theoretical models and field and laboratory experiments; mutualism is generally treated in a perfunctory way.

As I have suggested elsewhere2, there may be two main reasons for this relative neglect of mutualistic interactions. On the theoretical side, the simple mathematical models developed in the 1920s and 1930s by Lotka, Volterra, Kostitzin and others do capture some of the essential features of competitive and predator-prey dynamics, but they lead to nonsense for mutualism. On the empirical side, the conspicuous mutualistic associations tend to be tropical ones, whereas until relatively recently the bulk of ecological research was done in temperate regions (as a glance at, for example, the cumulative index in the Journal of Animal Ecology3 will show); temperate zone mutualisms certainly exist, but - as we shall see below - they can be more subtle than tropical ones.

Models of mutualistic associations

The non-linear Lotka-Volterra equations describe the interactions between two species in such a way that the per capita birth rate of species A depends linearly on the population densities of species A and of species B. In mathematical terms, this means the 'isoclines', which partition the dynamical behaviour of the populations A and B into various qualitatively distinct regions, are straight lines. For competing species, the results can be victory for species A, or for species B, or

coexistence; more sophisticated models give broadly similar behaviour. For predator-prey, the outcome is a propensity to cyclic oscillations, which again gives the key to the behaviour of more refined models. But for mutualisms that are sufficiently strong, these simple models lead to both populations undergoing unbounded exponential growth, in an orgy of reciprocal benefaction.

As reviewed at the Symposium by Post, a variety of recent analyses have sought to remedy this defect^{2,4-6}. In essence, all these studies observe that the benefit conferred by one species on another will eventually saturate to some limiting value, set by resource or other constraints. The resulting curvilinear isoclines must interesect, giving some finite population level for the mutualists. At the Symposium, Culver⁷ described a specific instance in which the limits to a mutualism (between ants and some spring herbs whose seeds the ants disperse) are apparently set by rodent seedpredators. In many of these models, the mutualistic equilibrium is one where, although both species are more abundant than they would be in the absence of mutualistic effects, both are more dynamically fragile - more prone to fluctuate and taking longer to recover from a given perturbation. On the other hand, as discussed by DeAngelis et al.8, in a patchy environment the mutualistic association between plants and seed-dispersers can act as a stabilizing influence.

Another complication arises when one (or both) of the mutualistic species comes to be 'obligate', in the sense that the population cannot persist in the absence of its partner^{2,4,9}. In this circumstance, there can be two alternative stable states, one with both species present in numbers enhanced by their association and another in which the obligate species is absent (or both are absent if both are obligate). These two alternative states are divided by a 'watershed' of population values, and environmental disturbances can carry the system from one state to the other; in practice, the more likely excursion will be from the state with both species present to the state in which one or both species are absent. An example of such a situation is given by Soberon and Del Rio9, whose model for the association between plants and highly specific pollinators shows that the conditions which optimize the production of nectar tend to diminish the stability of the association.

Elaborating a general notion introduced by Levine¹⁰, Vandermeer described how

Robert M. May is Class of 1897 Professor of Zoology at Princeton University, New Jersey 08540

effectively mutualistic interactions can arise indirectly in complex food webs11. Suppose species A and B appear to compete for prey species C and D, with species B concentrating mainly on resource D. Suppose further that species C is competitively superior to D and would eliminate D were it not for the effects of the predatory species A. It now can happen that removal of species A will lead to the prey species C displacing D, thus decreasing the population of B which is sustained largely by D. Thus the apparently competing species A and B are, in fact, mutualistically related, by virtue of these 'indirect' interactions. As Vandermeer showed, when realistic time lags are added on top of these indirect effects, the dynamics of mutualistic associations can become very complex indeed. There is clearly much room for further theoretical

Empirical studies of mutualism

Many beautiful studies have recently been carried out, analysing the energetic costs and benefits involved in the association between nectar-producing plants and their pollinators. The plant-pollinator systems are mainly tropical, and often obligate¹²; the pollinators embrace butterflies^{13,14}, hummingbirds and sunbirds¹⁵⁻¹⁷, bats^{18,19}, bees^{20,21}, lemurs and marsupials²². Likewise, recent work on some tropical associations between plants and seed-dispersers has not only analysed costs and benefits, but has shown the longterm dangers inherent in obligate mutualisms. Thus, unless we intervene, the Calvaria tree looks like following to extinction the dodo that once dispersed its seeds23. More generally, the neotropical flora may still be changing in response to the disappearance of many large mammals from South America²⁴. Fascinating though these studies are, here we will concentrate on mutualisms involving plants, anttended insects and ants.

The tropics afford many striking examples of obligate ant-plant associations, in which plants provide both food and housing (in special 'apartment-like' physical structures at the base of thorns or elsewhere) for ants. In temperate regions, associations in which plants offer food (but not housing) exist, albeit less conspicuously.

Inouye and Taylor²⁵, for example, have shown that Aspen sunflowers possess extrafloral nectaries that attract ants. By excluding ants from some plants, and by other manipulative experiments in the field, these authors have demonstrated that the ants confer reciprocal benefits on their host plants, by providing a degree of protection against herbivorous predators. In a similar set of carefully designed field

experiments, Tilman²⁶ has shown that the extra-floral nectaries on black cherry trees attract a species of ant, which in turn helps check the depredations of tent caterpillars. A variation on this theme is provided by Messina's work²⁷ on the ant species attracted to goldenrod by the nitrogen-rich 'honeydew' they can get from tending membracids (tree-hoppers) that are feeding on the plant; as observed by Bristow²⁸, in such circumstances the phytophagous insects are a kind of portable extra-floral nectary. Here Messina's manipulative experiments again show that the ants help to exclude other herbivores from the plant.

The above studies carefully document the costs and benefits of the ant-plant association. On the other hand, they typically do not wrestle with the complexities of food web structure, often lumping different ant species together as 'ants'. The complications that can arise in unravelling the full community structure of an ant-homopteran-plant association is well illustrated by the pioneering work of Addicott²⁹: at his study site, fireweed supported four species of aphids, of which three were tended by a total of ten species of ants. This detailed investigation of community structure is, however, largely descriptive.

Of particular interest, therefore, are some recent studies which combine manipulative and analytical techniques with full dissection of the structure of the community. One such study, involving carrion-burying beetles and hitchhiking mites, was described at the Symposium by D.S. Wilson; a full report of this complex story will be given another time. Another such study involves — in its essentials — a

membracid and an aphid species that feed on ironweed in New Jersey. These homopterans are tended by two ant species, a Myrmica and a Tapinoma. Using controlled experiments in the field and in a greenhouse, Bristow²⁸ has elucidated the detailed structure of this community, along with the costs and the benefits of the association to both ants and homopterans. Under favourable conditions, there is a strong tendency towards specialization by the ant species: Myrmica prefers membracids, and Tapinoma prefers aphids. This tendency is, however, far short of an obligate dependence: the preferences are not exclusive, and either species of ant will tend either species of homopteran. Bristow²⁸ goes on to observe that in temperate zone systems, absolute dependence is often too costly. Winter forces a prolonged break in any association, in time and perhaps also in space; species exploiting ephemeral hosts must

find new hosts at least once each spring, and possibly more often. Ants cannot rely on their highly localized foraging area being recolonized by their preferred honeydew producer. By the same token, homopterans may find themselves abandoned if the ants move for some reason.

Bristow²⁸ concludes by suggesting a new paradigm for mutualistic associations outside the tropics:

"The interesting point is not that temperate zone mutualisms are rarely obligate, but rather that by relying on simple environmental cues and behavioural mechanisms a high degree of fine tuning may be achieved with almost no loss of flexibility. This suggests that facultative mutualisms may deserve a closer look than they have received; their contribution to community or guild structure may not be as negligible as has been previously presumed."

Type I supernova thermonuclear versus collapse

from Stirling A. Colgate and Albert G. Petschek

In a recent issue of Nature, Canal, Isern and Labay1 discussed the rather esoteric problem of the evolution of a type I presupernova core - a white dwarf star where a eutectic phase separation of carbon and oxygen is presumed to take place before explosion. This would seem to be a singularly esoteric and even abstruse issue. but such are the labyrinthian relationships in science that this topic is central to a major issue in astrophysics - the mechanism of supernovae. It depends in turn on the most mundane property of metals - the alchemy of alloys and the long-range order functions of the fluidsolid transition, a controversial topic in theoretical physics. The same problem arises in the analysis of ordinary materials as well as of y bursts.

A supernova — the explosion of a star is the most dramatic real-time event that we observe in the Universe. Presumably, most of the elements necessary for life are generated and dispersed within the Galaxy by such an event. Presumably also, the most exotic energy and state of matter. cosmic rays and neutron stars, are formed in a proportion of such events. Yet there is no universal agreement as to the mechanism(s). The large star, \sim 10 solar masses (M_{\odot}) , almost certainly makes a type II supernova, leaving a neutron star remnant. The collapse and subsequent explosion is currently modelled by the elastic bounce energy of the forming neutron star core^{2,3}. In the past, neutrino emission was thought to cause the explosion that accompanies collapse, but now neutrinos are believed to hinder the

propagation of a mass-ejecting shock. The theoretical outcome, that is, explosion or collapse to a black hole, is still dependent upon details. The need to resolve this unhappy uncertainty has stimulated considerations of possible different neutrinomatter interactions, such as axions4 and Majorana coupling⁵. Violent neutron star convection has also been considered by Colgate and Petschek6, and refuted by Lattimer and Mazurek7.

Type I supernovae are believed to be older, less massive stars that ignite a thermonuclear reaction in the core and are pushed over the edge of degeneracy stability - the Chandrasekhar limit - by a combination of slow accretion from a binary and evolution. If a carbon core ignites early at the low density of $2-5 \times 10^9$ g cm⁻³, then the star explodes from a thermonuclear deflagration and no remnant is left. However, if an oxygen core thermonuclearly ignites at the higher density of $\sim 2 \times 10^{10}$ g cm⁻³, then rapid electron capture decreases the degeneracy pressure faster than thermonuclear deflagration drives expansion, and collapse to a neutron star occurs8. We are then left with the same difficulty - how does a type II supernova work? Nevertheless, we can predict that a carbon deflagration disintegrates the star and ejects all the matter (1.41 M_☉), mostly as iron, into the Galaxy. An oxygen deflagration and collapse would eject

Stirling A. Colgate and Albert G. Petschek are at the Los Alamos National Laboratory, Los Alamos, New Mexico 87545.

about one-fifth as much. This latter case is more comfortable for galactic theorists but comfort is not everything9. The light from the supernova comes from the subsequent ß decay energy of 56 Ni that decays to stable iron (56Ni 6.6 day 56Co77 day 56Fe). The classic observed optical decay half life of 56 days of supernovae I10 is powered by the radioactive decay positrons from ⁵⁶Co. An increasing proportion of the β^+ can escape and simulate a 56-day exponential provided the ejected mass is relatively small. The larger ejected mass resulting from carbon deflagration models requires a critically timed IR emission11 if agreement with observation is to be obtained. The positrons, which were once observed at the galatic centre and now seem to have disappeared^{12,13}, would have had the correct flux if the source were a supernova type I involving collapse with the escape of 10 per cent of the positrons.

Helium burning in the pre-supernova white dwarf star leads to roughly a 50:50 mixture of fluid carbon and oxygen at a density of 108-109 g cm⁻³. A eutectic exists in the phase diagram (66.8 per cent 12C and 33.2 per cent 16O), as in a lead-tin solder. On energetic grounds, the smaller atom or ion prefers to fill the interstices of the lattice of the larger one and this lowers the melting point. The excess component, 16O, precipitates out as 16O snowflakes or perhaps as glass-like spherules and falls to the centre of the star. A further separation may occur after remixing of the remaining fluid due to a gravitationally induced thermohaline instability. Depending on the degree of separation of the core, an oxygen-rich core in the white dwarf will lead to a collapse, not a thermonuclear disintegration.

The energetics of the liquid-solid transition of matter is modelled in extensive Monte Carlo calculations that lead to melting point predictions¹⁴. Crystallization, on the other hand, requires additional physics for the transition to take place and has not yet been modelled numerically. The possibility of a neutron star quake leading to a neutron star volcano and subsequently a y burst depends on the same physics of the melting transition of neutron star crust matter¹⁵.

Struggles among the dunes

from Peter D. Moore

THE manner in which one plant paves the way for another in the course of vegetation succession may sometimes have its ironic aspects. So often, a colonizing plant species nullifies the effect of a severe environment only to find that, in doing so, it has made possible an invasion by a competitor that brings about its own local extinction.

Take, for example, a habitat which is close to the hearts of all students of succession — the sand dune. In West European dunes, the grass Agropyron junceiforme is the most conspicuous primary colonist of sands around high-water mark, being tolerant of high salinity (up to 6 per cent according to Salisbury1) and prolonged immersion. As it grows it creates wind eddies and encourages local sand deposition, and so raises minor dunes around itself. The sand surface rises further and further above the sea, until Ammophila arenaria, the marram grass, which has a lower salinity tolerance (about 2 per cent), is able to invade. The higher stature and aggressive, tussocky growth of the marram grass leads rapidly to its dominance. The subsequent decline of Agropyron seems simply to reflect its failure in the struggle for survival under competitive conditions.

At this stage many annual plant species invade and much consideration has been given to the factors which limit their establishment ¹⁻³. The young dune-front is exposed to adverse conditions but they become less severe as succession proceeds; salt-spray, shifting and unstable sands, low water availability and high diurnal temperature amplitude all may play their part.

Van der Valk4, for example, found the seedlings of invading forbs to be more sensitive to sand accretion than to any of the other above factors. In Cape Hatteras, North Carolina, 20-30 cm of winter sand is deposited on the coastal foredunes. But the seedlings can cope with only 5 cm of sand and their seeds with burial by 1-16 cm, so forbs can invade only when the major dominants, such as Ammophila breviligulata, have stabilized ridges and produced sheltered locations within the developing undulations and hollows. In the same way, A. breviligulata's European counterpart, A. arenaria, produces stabilized dune systems in the European coastal fringe, which support a high diversity of adventive species⁵.

What is very much less clear, because of the difficulty encountered in subjecting any given hypothesis to experimental testing, is why the major dominants like Agropyron and Ammophila become less

Peter D. Moore is a Senior Lecturer in the Department of Plant Sciences, University of London King's College, 68 Half Moon Lane, London SE24 9JF.

vigorous, flower less frequently and finally die out as the succession proceeds. The obvious answer is that subsequent species have greater competitive ability. But this does not always hold true, for the demise of Ammophila in older, stable dunes may not be accompanied by aggressive dominance of the system by robust newcomers. Moribund marram is often surrounded by a short turf vegetation rich in lichens and mosses which do not seem to offer a serious competitive threat; sometimes the declining Ammophila populations are accompanied by very little vegetation at all⁶.

Obviously other factors than competition are at work. Salisbury1 considered increased soil compaction and acidity as possible influences but it was Marshall7, whilst working on another sand dune grass. Corynephorus canescens, who hit upon a rather surprising answer. He found that burial of Corynephorus tufts encouraged the growth of new adventitious roots from tillers of grass and caused its tussocks to spread and proliferate. It grew well under conditions where sand accretion amounted to 10 cm per annum, but became moribund on stable sand and failed to generate new roots. The direct effect of burial was to increase the humidity around the tillers necessary for healthy root growth. Hope-Simpson and Jefferies⁶ confirmed many of the points made by Marshall concerning root growth for Ammophila, except for one piece of evidence. When planted in a Bristol garden Ammophila grew luxuriantly, both in foliage and root, and flowered freely despite the stability of the

Recently, interest has developed in another dominant plant of dune successions, the sea buckthorn, Hippophaë rhamnoides. It is undoubtedly a native plant in Britain8, but its frequency in coastal dunes, especially in the west, is probably a consequence of deliberate planting to stabilize sand9. It is a shrub which lives for about 40 years 10 and has root nodules in whch symbiotic nitrogen fixation occurs11. Its growth can, therefore, have considerable ecological consequences and raise ecosystem nitrogen levels by up to 179 kg ha-1yr-1 in sand dunes¹². Stewart and Pearson, who conducted studies on the nitrogen-fixing capacity of Hippophaë, noted that nodules on the youngest plants were most active in fixation.

On dunes in the Netherlands, Hippophaë enters a degenerate phase in older dunes, in a similar way to Ammophila. Oremus and Otten¹³ grew vigorous, young Hippophaë in soils from young embryo dunes and from stable sites where the Hippophaë was in a post-optimal state of development. More root nodules

were produced in the embryo dune soil and there was a higher rate of nodule death and necrosis in the mature dune soil. Root growth generally was poorer in the mature soil, roots were darker and root hairs fewer. Gamma irradiation of the soil samples before planting removed these root effects and healthy root systems developed on the plants even when grown in mature dune soils, which suggests that an organism within the soil was responsible for root stunting. A possible culprit was considered — the nematode Longidorus. It is absent in the embryo dune soil, but common in that of the mature dune and belongs to a genus known to cause root damage among many plants.

Several possible developments suggest themselves from this work. First, this knowledge of the susceptibility of Hippophaë to Longidorus infection, if confirmed, could provide a technique for the biological control of Hippophaë in those sand dune nature reserves where sea buckthorn has proved a pest by forming such dense and invasive patches that overall species diversity has been

reduced10. Second, the role of soil fauna in other cases where vigour declines as soils mature, such as Ammophila, needs to be investigated. It could account for the healthy growth of marram in the stable gardens of Bristol. Third, the work should serve to underline the potential importance of the soil biota, both faunal and microbial, in influencing competitive interactions and succession in the field.

Somatic gene amplification during Drosophila oogenesis

from David Ish-Horowicz

THE construction of an egg can make large demands on macromolecular synthesis. especially for organisms in which oogenesis is particularly rapid. Such is the case for Drosophila melanogaster, in which oogenesis takes only 2.5 days and as many as two to three eggs an hour can be laid. The intense synthesis of oocyte components is mainly achieved in cells whose DNA content has been amplified up to 1,000-fold by an increase in chromatid number per chromosome (polytenization). Two recent papers 1,2 show that, in addition to a 45-fold polytenization of the chromosomes in the follicle cells producing the eggshell, there is a further novel mechanism to boost synthesis: a localized differential polytenization of the gene clusters coding for eggshell components.

The protective eggshell, or chorion, contains about 6 major and 14 minor proteins that are synthesized over about 5 hours in a characteristic order that reflects the shell's complex multilayered structure3,4. Two years ago Spradling and Mahowald⁵ showed that the chorion genes are selectively amplified in follicle cell nuclei but not in other tissues. Using cloned cDNA and genomic DNA fragments two clusters of chorion genes were studied: one mapped to the X chromosome within

David Ish-Horowicz is in the Imperial Cancer Research Fund, Mill Hill Laboratories, Burtonhole Lane, London NW7 1AD.

bands 7F1,2 and includes the genes for proteins s36-1 and s38-1 and two related but uncharacterized genes⁵⁻⁷; the other cluster derives from the third chromosome (between bands 66D11 and -15) and encodes proteins s15-1 and s18-1 and includes two other genes 7.8. Each cluster is expressed for only 1-2 hours and appears to be coordinately regulated^{4,6}.

Comparison of egg chamber DNA with that from other male and female tissues showed5 that, in addition to the polytenization, the s36/s38 cluster is amplified about 12-fold, and the s15/s18 cluster is amplified about 60-fold. Differential replication is maximal at stages 11-13, the time of chorion protein transcription. At typical rates of transcription, about a 10-fold amplification would be needed to make the observed levels of s36 mRNA in 2 hours5, suggesting the extra genes are necessary to make sufficient chorion proteins.

Two possible models of amplification were suggested: additional extrachromosomal chorion genes, or localized differential polytenization. The two recent papers strongly support the latter explanation.

Spradling1 examined the regions surrounding each cluster and showed that the amplification extends well beyond the chorion genes. Even as far as 40 kilobases (kb) away from the cluster, he finds two-to fourfold amplification. Maximal amplification occurs at the chorion genes, with a steady decline in more distant regions, consistent with a replication origin mapping close to the cluster. The steady decrease in amplification suggests the replication terminates randomly rather than at occasional discrete sites. He confirmed the absence of specific termination sites by using Southern transfer hybridization to look for restriction fragments with an altered electrophoretic mobility. No such differences between amplified and nonamplified DNA were found.

Elegant confirmation of the model is presented in the second paper2 where Spradling and Mahowald studied a femalesterile mutation occelliless (oc)9 caused by a 10-band chromosomal inversion which breaks the s36/s38 cluster, transposing most of it next to sequences in 8A1,2. The mutation drastically alters the pattern of amplification, as if the inversion has transposed a cis-acting replication origin. The inverted chorion genes are still amplified and the replication spreads into the adjacent and previously unamplified 8A1,2 sequences. In contrast, the uninverted 7F1,2 sequences (including at least one chorion gene) are no longer amplified. The replication origin must thus be in the proximal part of the cluster and, indeed, this is the first strong evidence for a discrete eukaryotic chromosomal replication origin. As well as disrupting the pattern of amplification, the oc inversion reduces s36 and s38 amplification twofold by inhibition of the last round of somatic amplification. The consequent reduction of s36 and s38 synthesis may contribute to the female sterility (which is due to defective eggshell production¹⁰), but other reasons may include the inability to amplify the untransposed chorion gene.

Is tissue-specific gene amplification during development a common mechanism for selectively enhancing gene expression? This may be the case in Drosophila where many, if not most, differentiated tissues

are polytene. A long-standing example comes from the salivary glands of Rhynchosciara where DNA amplification of a chromosome band (DNA puffing) precedes its transcription¹¹. In this case, the trigger for DNA replication is the steroid hormone ecdysone¹². Perhaps chorion gene amplification in Drosophila is also under hormonal control although there is only suggestive evidence for this. Both ecdysone and juvenile hormone have been implicated in regulating vitellogenesis in Drosophila^{13,14}, which occurs at the same stages as the chorion gene replication. Drosophila mutants that are temperature sensitive for larval ecdysone production are also temperature sensitive for female fertility and eggshell production 15,16 but the latter effect appears associated with follicle cell degeneration¹⁷. As chorion maturation has been demonstrated in cultured ovaries¹⁸, the role of hormones in triggering somatic chorion gene replication is now accessible to *in vitro* study.

It is doubtful that tissue-specific gene amplification is very general. The chorion of the silkmoth *Bombyx mori* is also secreted by surrounding follicular cells, but its proteins are made from over 100 linked genes^{19,20} that are not thought to be somatically amplified. Indeed, a host of other intensely transcribed genes are single copy in expressing cells. Presumably, the rarity of somatic gene amplification reflects the ability of a single protein-coding gene to cope with heavy synthetic requirements, except under the most demanding circumstances.

Some like it hot: temperature-determined sex

from Paul H. Harvey and Montgomery Slatkin

Most biologists are familiar with chromosomal sex determination. Mammals with both an X and a Y chromosome develop as males while those with two X chromosomes develop as females. In birds the arrangement is reversed and females are the heterogametic sex. Some reptiles, amphibians and fishes also possess sex chromosomes which determine whether the zygote develops as a male or as a female!

Genetically controlled determination has generally been assumed to have a remote ancestry in the vertebrate lineage, but recently a quite different sexdetermining mechanism has been discovered. Sex in many reptiles is now known to be not genetically controlled but determined by the incubation temperature of the zygote during embryogenesis².

The first case of temperaturedetermined sex was recognized in 1966 for a lizard3, and others appeared among turtles in the 1970s4,5, but it was not until 1979 that Bull and Vogt6 ruled out the possibility that differential mortality dependent upon temperature was the source of the sex-ratio bias. In their study of five species of turtle, they were further able to show that, in four of the species, sex ratios in the wild resulted from the degree of exposure of the nest to sunlight and hence to the incubation temperatures. In the fifth species, sex determination was not temperature dependent. Among reptiles, temperaturedependent sex determination is now known or suspected in alligators, two species of lizards and many turtles2 (including sea turtles7 - with important implications for conservation measure for endangered species). Most reptiles have yet to be studied.

Incubation temperatures can have a despecie offset on severatio bias. In many

incubation of eggs in the laboratory as a

dramatic effect on sex-ratio bias. In many turtles, low temperatures (20-27°C) produce only males, high temperatures (30-35°C) produce only females and there is a narrow temperature range producing both sexes. Lizards show the opposite pattern with low temperatures causing eggs to develop as females, and high temperatures as males. Snapping turtles (Chelydra serpentina) show yet a different pattern of response: females develop at high and low temperatures (20 and 30°C) and males in between. But natural nest sites fluctuate in temperature. In a laboratory experiment subjecting map turtle (Graptemys) eggs to daily temperature fluctuations between different all-male and all-female extremes (20-30°C and 23-33°C)6, the broods raised between the lower temperatures produced only males, and those between the higher temperatures

In species which have heteromorphic sex chromosomes (those recognizable under a microscope), it seems that the environment does not also determine sex, that is, individuals which deviate from the usual association of XX with one sex and XY with the other are not observed (for a review, see ref. 2). There may, however, be a genetic component to temperaturedetermined sex. In the Atlantic silverside (Menidia menidia)8, low temperatures produce more females but eggs from the broods of different females show different temperature-response curves. Similar, though less extreme effects have been noted in turtles9.

Little is yet known about how tempera-

ture controls sex determination. The sensitive period lasts some weeks during the middle of development in turtles 10-12 and occurs about 46 days after hatching in the Atlantic silverside. Temperature may thus be acting during gonadogenesis. H-Y antigen, a cell-surface component suspected of having a primary role in gonadal sex determination in vertebrates (the heterogametic sex is H-Y positive)13, has been studied in fourteen turtle species14. In thirteen species the female was typed as H-Y positive, and in the other species (Chinemys reevesi) the male was H-Y positive. Unfortunately, very few individuals of each sex were typed (between one and three) and so the data do not provide firm evidence for a completely sexdifferentiated response. Indeed, in two species the male was not typed and a previous study had shown that, in a third species (Emys orbicularis), both males and females could be either H-Y positive or H-Y negative¹⁵. This species shows temperature-dependent sex determination, so the results suggest that H-Y antigen does not control sex differentiation in this species. If the findings are correct and eventually hold for gonadal cells (the quoted experiment was performed on blood cells), this constitutes a major departure from the supposed ubiquitous role of H-Y antigen in vertebrate sex determination.

Temperature-dependent sex determination poses both demographic and evolutionary puzzles. What, if anything, prevents large variations in sex ratio in both space and time as developing broods respond to different climatic conditions? Bull and Vogt16 compared sex-determining temperatures among embryos of map and painted turtles collected from the northern and southern United States and predicted that embryos from southern populations should develop as males at higher temperatures than those of northern populations. Interspecies comparisons provided no support for, and intraspecific comparisons (on two species where this is possible) actually went against, the hypothesis. If this is generally true, then there is no local adjustment of the temperature-dependent mechanism through zygotic means. Populations will then exhibit large geographical differences in sex ratio unless some compensatory mechanism, such as varying the choice of nest sites or emigration, adjusts the adult sex ratio.

Why has temperature-dependent sex determination evolved? If environmental conditions cause a large excess of one sex, then, following Fisher¹⁷, any mechanisms that reduced the excess would be favoured by natural selection. Charnov and Bull¹⁸ have argued that environmental sex determination (of which temperature-determined sex is one case) would evolve when conditions experienced during some stage of development have a strong differential influence on the fitnesses of

Paul H. Harvey is a lecturer in Biology at the University of Sussex, Falmer, Brighton and Montgomery Slatkin is an Associate Professor in Zoology at the University of Washington, Seattle, Washington 98195.

adult males and females. For example, larval mermithid nematodes become female in response to high levels of nutrition (in large hosts), but become male under low levels of nutrition. The explanation is that the large individuals, that can develop in large hosts, can produce more offspring as females than as males. At present, it is not clear whether such effects exist in reptiles but a new study of alligators (see this issue of Nature, p.850) suggests that they may. Incubation temperature indirectly affects the animals' growth rate by influencing the amount of yolk remaining at hatching. Large size early in life is apparently more beneficial to females than to males.

Temperature-determined sex may indeed be the ancestral condition for reptiles. It is known in three of the four living orders: turtles, snakes and lizards, and crocodilians (the tuatara, the surviving representative of the Rhyncocephalia, has not been studied). Morphologically distinguishable sex chromosomes are found in only two orders (the turtles and the snakes and lizards), but it is uncertain

whether genotypic sex determination originated once or more than once². If temperature-determined sex is ancestral for reptiles, and if the birds and mammals arose from such a reptilian stock, then we are left with a radically different view of the evolution of sex determination in the vertebrates.

An Arctic Ocean ice sheet in the Pleistocene?

from L.D. Keigwin

An intriguing and controversial suggestion stemming from recent palaeoclimatic studies is that the Arctic Ocean was covered by a massive floating ice shelf during the last glacial maximum. The idea has been put forward from evidence of 618O fluctuations in deep-sea cores and in ice cores on Greenland1 and has been proposed as a solution to problems in Arctic glacial dynamics and chronology².

A recent paper by Williams, Moore and Fillon³ now puts the floating Arctic Ocean ice shelf hypothesis in a timestratigraphical framework for the entire Pleistocene, and for the last 150,000 years in particular, by comparing inferred sea levels from the δ^{18} O records of the deep sea with the record of sea level given by raised coral terraces. They found significant differences in the apparent sea level calculated from the two data sources which they attributed to the presence of a floating ice shelf that would produce the change in seawater isotopic composition without significantly altering sea levels. The authors conclude that ice shelves may have originated as important features earlier in the Quaternary.

Oceanic 818O records have been observed to change from high-frequency, low-amplitude to low-frequency, highamplitude variability about 900,000 years before present. Williams et al. argue that at that time the Earth's orbital parameters

changed and allowed the first combined accumulation of massive ice shelves and sheets in the Arctic.

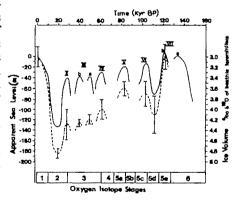

For the Quaternary it is widely held that δ18O changes of 0.10°/00 in deep-sea benthic foraminifera correspond to sealevel changes of 10 m (based on a mass balance assuming average δ^{18} O values of glacial ice4). A similar relationship has been derived from 618O variations in corals from uplifted terraces⁵. The only known way rapidly and greatly to enrich the ocean in ¹⁸O is by removing isotopically lighter ¹⁶O from the ocean through evaporation and precipitation. A fall in sea level will result if the precipitation is stored on continents as ice, but not if it is stored as a floating ice shelf. The 518O of deep-sea benthic foraminiferal calcite depends on the temperature and isotopic composition of the seawater and so-called 'vital effects', but most of the 1.7% o glacial-interglacial δ¹⁸O change in the ocean can be attributed to seawater compositional changes caused by increased ice volume. Vital effects can be reduced by analysing single species of benthic foraminifera and the effect of changing deep-sea temperatures on 618O records is generally discounted because the total amount of isotopic change would

L.D. Keigwin is at the Woods Hole Oceanographic Institution, Woods Hole, Massachusetts represent a cooling of most of the deep sea below freezing.

Sea-level records based on raised coral terraces are not continuous, but can be dated. Constant rates of uplift have been assumed and, where reasonable, a composite sea-level record has been derived. Williams et al. compared such a composite terrace record with a composite deep-sea record for the late Ouaternary3 to arrive at their conclusions. Other sea-level indicators, however, do not always agree with the raised coral terrace record.

Hollin6 has provided evidence for a dramatic rise in sea level about 95,000 years ago which may be due to an Antarctic glacial surge. If such events occur in less than the 1,000 year mixing time of the ocean they may not be resolved in the deepsea stable isotopic record. The greatest apparent sea-level differences between the generalized records of Williams et al.3 are between about 20,000 and 100,000 years ago where they differ by 30-80 m. To produce a 50 m sea-level difference the area of the Arctic Ocean would have to be covered by a floating ice shelf 1,300 m thick, close to the mean depth of that ocean. Even if adjacent seas and part of the North Atlantic are included, hundreds of metres of ice shelf are still required.

Alternatively, the 50 m sea-level difference (equal to a difference of $\sim 0.50\%$ could be accounted for by a deep-ocean cooling of 2°C. Williams et al. have not given this possibility emphasis because of ambiguities in inferring bottomwater mass history from benthic foraminiferal distributions. Studies of cores under Antarctic bottom water show faunal changes that do not follow a simple glacialinterglacial pattern^{7,8}, but studies of cores beneath deep waters (Circumpolar and

Comparison of apparent sea-level records from raised coral terraces (solid line) and benthic foraminiferal oxygen isotope records (dashed line). The isotopic record is a composite of results from five Atlantic, Indian and Pacific Ocean deep-sea cores and error bars represent one standard deviation about the mean at various times. Vertical scales are adjusted so that a 1.1% of 18O change equals a 10 m sealevel change. Sea-level differences between the two records of as much as 80 m may result from ice shelves which could change the isotopic composition of the ocean without significantly lowering sea level, and from cooler deep-sea temperatures during glacial intervals.

North Atlantic deep water) do show glacial-interglacial faunal oscillations, suggesting water mass changes 9,10. The isotopic data examined by Williams et al. are based on sediment from cores of relatively shallow water depth (< 3,300 m) within deep-water masses. Deeper cores generally have lower sedimentation rates because calcite dissolution increases with depth; thus they have lower resolution. As such, most cores from which isotopic data have been reported actually could have 2°C glacial-interglacial changes in deep-water temperature.

Deep-sea cooling could be eliminated from consideration by studying stable isotopes in cores where deep-sea water is less than 2°C from freezing. Water mass changes could also significantly affect the interpretation of benthic foraminiferal isotopic records as ice volume-sea level indicators because the range of the principal modern deep-water masses is about 0.6%. For example, a seawater compositional change of this size could result from replacing North Atlantic deep water by Antarctic bottom water at the transition from an interglacial to a glacial interval. Recent stable isotopic and geochemical studies of cores within the Atlantic suggest reduction or elimination of North Atlantic deep water during glacial intervals11-14.

Regardless of the uncertainties in interpreting foraminiferal 818O data, some glaciologists have hypothesized that during glacial extremes there were massive ice shelves associated with an Arctic ice sheet^{2,15,16}. This controversial hypothesis is based on analogy with the Antarctic ice sheet, a large part of which is currently grounded below sea level. Central to the idea2 is the role of ice shelves in explaining the location, mode and sequence of formation of most Northern Hemisphere ice domes. Briefly, Hughes et al.2 propose that massive ice shelves form when ice streams coalesce and the shelves buttress and allow the growth of massive domes. The shelves must form before the domes, so the largest ice volume growth in the late Quaternary would require ice shelves.

The work of Williams et al. has focused attention on the debate about the extent of floating Arctic ice during glacial intervals. Although evidence from Arctic Ocean cores indicates perennial sea-ice cover began 700,000 to 900,000 years ago17, it is difficult enough to prove the existence of massive ice shelves during the last glaciation, not to mention earlier in the Ouaternary. Further studies of deep-sea cores, including cores from the Arctic may help resolve the problem.

The key to the schistosome's success

from A.J.G. Simpson and D. Cioli

SCHISTOSOMIASIS or bilharzia is a disease affecting some 200 million people in the developing countries. The causal agent is a parasitic worm, the schistosome, which lives in the blood vessels of the intestine or urinary tract; man becomes infected by the cercarial, or free-living aquatic, stage which penetrates the skin directly. The key to understanding how host immunity is effected and how the worm evades this response is to learn more about the schistosome's double outer membrane (DOM). This unique surface not only mediates crucial metabolic functions but also counteracts the immune system of the host. Progress in this field was reported at a recent meeting in Geneva*.

The techniques of subcellular fractionation are providing an invaluable approach to the characterization of the DOM. It can be selectively released from the parasite simply by brief incubation in buffered saline at 37°C (Evans, NIMR, London), by using freeze-fracture techniques (Wilson, University of York), or by utilizing the negative surface charge of the parasite as the basis of membrane purification (Cesari, Instituto Venezolano de Investigaciones, Caracas). An alkaline phosphatase of broad specificity has been widely used as a marker for the DOM and enrichment of specific activity for this enzyme has been reported, by all investigators, in fractions shown to contain DOM by morphological observation or in those enriched in externally applied ligands.

Wilson and Podesta (University of Western Ontario) have further dissected the DOM by preparing separate fractions enriched for the inner and outer bilayers. Podesta utilized the sequential exposure of the parasite to 0.1 per cent digitonin solutions to obtain first the outer and then the inner bilayer from intact adult worms, a technique previously used in the preparation of mitochondrial membranes in other systems. The outer bilayer fractions had very low enzyme activities, suggesting that membrane-bound enzymes are associated predominantly with the inner layer of the DOM.

The surface of the schistosome represents the primary target for immune attack. As the schistosomulum (the immature worm) is the most susceptible stage, attempts to determine target antigens have largely been conducted by surface labelling this stage. Several participants reported results carried out by a variety of techniques. As many as ten or more proteins of molecular weight 18,000-200,000 may be labelled on schistosomula. There is, however. variation in the polypeptides labelled by the various procedures, and Cioli (Consiglio Nazionale della Richerche, Rome) has shown that the most selective and gentle methods identify an 18,000 molecular weight polypeptide. Not all polypeptides can labelled immunoprecipitated with sera from patients or infected animals and the reported molecular weights of major precipitated antigens vary considerably.

Taylor (University of Cambridge) used iodosulphanilic acid to label the schistosomulum and immunoprecipitated polypeptides of molecular weights 185,000, 105,000, 68,000 and 24,000 with sera from infected humans. Dissous (Institut Pasteur, Lille) immunoprecipitated polypeptides of 40,000, 37,000 and 32,000 with immune rat sera following lactoperoxidase-catalysed iodination of the schistosomular surface. Both of these investigators reported the production of monoclonal antibodies which recognized defined surface antigens (Taylor molecular weight 24,000, Dissous -37,000) and detected some in vitro activity with their monoclonal reagents. Dissous further reported the passive transfer of immunity to rats using her monoclonal antibody.

How is the DOM of the developing parasite involved in immune evasion? Susceptibility to immunity is age dependent and as the parasite matures it quickly loses the ability to bind antiparasite antibody, a change which correlates with the detection of host deter-

minants on the parasite surface. Caulfield (Harvard Medical School) reported, however, that parasite antigens are spontaneously lost from young schistosomula in vitro, even in the absence of serum or other macromolecules. Thus, the loss of antigenicity may result from the active shedding of parasite surface components.

Membrane turnover and shedding (particularly in response to ligand and cell binding) may be generally involved in the protection of the parasites. Brink (Harvard Medical School) demonstrated the shedding of antibody-antigen complexes from in vitro cultured schistosomula, and Caulfield reported that following a unique membrane fusion between the schistosomulum and neutrophil membranes, whole areas of membrane may be lost to the cell interior, but the parasite survives and eventually the neutrophils are released. Kemp (Texas A & M University) has also detected immunoglobulins bound to the adult surface via their Fc portion, and if anti-Fab antibodies are bound to the surface immunoglobulins, the complexes are actively shed within 15 minutes. Freezefracture (Torpier, Institute Pasteur, Lille) shows that this is accompanied by the cross-linking of membrane components (visualized as intramembranous particles) into tetrads and their subsequent disappearance from the DOM.

Alterations in the chemical composition of the double outer membrane may result in its being refractory to the effects of cytotoxic mechanisms. When five-day schistosomula are recovered from mice

(McLaren, NIMR, London) they are coated with red blood cell antigens. If the parasite is exposed to eosinophils in the presence of anti-mouse red blood cell antibody, the cells bind to the surface and degranulate, but fail to kill the parasite although similar antibody-dependent cytotoxic mechanisms are potent killers of fresh schistosomula, and also of parasites three weeks old or more. Thus, even if the surface components of five-day old worms are recognized by antibody and cells, there is still an 'intrinsic' protection of the surface membrane of the parasite at this stage.

The presence of host antigen determinants on the parasite surface may be the result of an active evasion mechanism by the schistosome, whereby it synthesizes molecules that mimic those of the host and serve as a disguise. Among the molecules recognized on parasites recovered from mice are the products of the major histocompatibility complex. Simpson (NIH, Bethesda) reported that monoclonal reagents indicate that an intact H-2 antigen is present on the schistosome surface. Although analysis of the parasite genome demonstrated some DNA sequence homology between S. mansoni and its hosts, genes coding for either human or mouse histocompatibility antigens were not present, so these molecules must be acquired from the host.

In vitro experiments (Rumjanek, NIMR, London) demonstrated that lipid composition of schistosomula was profundly affected by the presence of serum which is able to stimulate intense

exchange of lipids between the organism and the medium. Fetal calf serum produces a net depletion of lipids, whereas human serum produces a substantial uptake of cholesterol and triglycerides. This seruminduced lipid modulation correlates with the degree of protection observed in in vitro cytotoxicity assays and furthermore, no protection is afforded by incubation of schistosomula in delipidated serum. This strongly implicates lipids as being responsible for the acquisition of resistance by the parasite to the immune effector mechanisms. The protective effect of serum may be associated (Torpier) with low-density lipoproteins, which bind to the parasite surface, and this may be the basis of the lipid changes observed by Rumianek.

It is clear that our knowledge of the physiological functions of the schistosome DOM is still very limited, but in view of the importance that understanding of the membrane may have for the development of immuno-prophylactic and chemotherapeutic agents, it was felt that increased research efforts should be made to define the molecular structure of specific membrane proteins. The use of monoclonal antibodies and recombinant DNA technology to clone and sequence the parasite genes coding for these components is most likely to provide the way forward. The expression in microorganisms of genes coding for surface antigens may be an important step towards the production of significant amounts of parasite antigens for vaccination.

100 years ago

No group of animals is more characteristic of the peculiar fauna of Australia than the great family of Honey-Eaters (Meliphagidae), of which upwards of sixty species, belonging to many different genera, are distributed throughout the length and breadth of that Continent. But although the Honey-eaters are so common in Australia, and there is an extensive importation of living birds from Sydney and other Australian ports every year into this country, very few of the Meliphagidae have yet reached Europe alive. The fact is, that the organisation of the Honey-eaters, being adapted for an active and wandering life, in perpetual search of the nectar of the flowering-trees which their pencilled tongue so admirably fits them to collect, does not render them very suitable subjects

for captivity, and it is only recently that means have been found to preserve these birds alive and in good health in cages. It has thus happened that almost the only one of the vast tribe of Australian Honey-eaters that has been exhibited in the Zoological Society's aviaries is the present species, which we now figure (Fig. 18) from four examples lately received from New South Wales.

In his great work on the "Birds of Australia", Mr. Gould tells us that the Warty-faced Honey-eater is not only one of the handsomest of its tribe, but also one of the most beautiful birds inhabiting Australia, the strongly contrasted tints of its black and yellow plumage rendering it a most conspicouous and pleasing object, particularly during flight.

Although very generally distributed, its presence appears to be dependent upon the state of the Eucalypti, upon the blossoms of which it mainly depends for subsistence; it is consequently only to be found in any particular locality during the season that those trees are in blossom. It generally resorts to the loftiest and most fully-flowered tree, where it frequently reigns supreme, buffeting and driving every other bird away from its immediate neighbourhood.

The Lobed Muskduck (Biziura lobata). — Waterfowl have always formed a favourite portion of the Zoological Society's living collection, and it is with great satisfaction that every new addition to the already long list of "acclimatisable" Anatidae is announced in their journals. The species which is now portrayed (Fig. 19) is certainly one of the most remarkable that they have yet procured, and although perhaps not likely to be "acclimatised" at present, is well worth examination as being remarkable even amongst Australian animals, for several very abnormal features in its structure.

The Musk-duck has a lengthened, stiff, and leather-like appendage hanging from the under surface of the bill, and is the only member of the

family which possesses this singular structure. its lengthened tail, composed of twenty-four narrowed and stiffened feathers, is, no doubt, most serviceable to it in swimming and diving. The female does not carry the chin-lobe, and is very much smaller than the male bird.

male bird.

The Musk-duck is widely distributed on the Australian Continent, and also inhabits Tasmania. It frequents the bays and inlets of the sea, the upper parts of rivers, lakes, and secluded pools. "More than a pair are rarely seen at one time; often a solitary individual takes up its abode in some favourite pool, where it lives a life of complete seclusion, depending for its food and for its preservation from danger upon its powers of diving rather than upon those of flying. It is very difficult to shoot, as it dives instantly a gun is fired, so that the shot has hardly time to reach it.

REVIEW ARTICLE

Actin-binding proteins—regulators of cell architecture and motility

Alan Weeds

MRC Laboratory of Molecular Biology, Hills Road, Cambridge CB2 2QH, UK

Numerous actin-binding proteins from a variety of cell types have been described. Here I attempt to correlate the properties and functions of some of these. Three major classes have been identified: (1) cross-linking proteins which form filament bundles or isotropic gels; (2) proteins which cap filament ends and nucleate the polymerization of G-actin (many of these also sever actin filaments); (3) proteins which bind to G-actin and stabilize the monomer pool. Some of the proteins described here combine the properties of more than one class and the activities of many of them are regulated by changes in Ca^{2+} ion concentration.

ACTIN is a major constituent of many types of eukaryotic cells and is involved in a wide variety of motile processes including cell locomotion, cytoplasmic streaming and transport, secretion, phagocytosis and cytokinesis. 'Stress fibres', consisting of bundles of microfilaments1 are clearly seen in spreading or moving cells and these contain myosin, filamin, tropomyosin and α -actinin in addition to actin²⁻⁵. Actin is also concentrated as a dense filament meshwork in the cortical cytoplasm⁶, finger-like projections (filopodia) and veil-like sheets of membrane (lamellipodia or ruffles) display the dynamic activity of the cell surface during movement. This cortical cytoplasm undergoes dramatic changes in viscosity and stiffness which reflect the formation of actin filaments and their assembly into more highly organized meshwork structures. An understanding of cell motility therefore requires detailed knowledge of (1) the structural components involved with actin in the formation and rearrangement of this cortical network; (2) its biochemical composition; and (3) the mechanisms by which the interaction of these individual proteins are regulated.

Over the past five years much effort has been directed towards these goals⁸⁻¹¹. Many new actin-binding proteins have been identified, initially in crude cell-free extracts, but many of these have now been purified and partially characterized. Particular progress has been made with cytoplasmic gels isolated from macrophages and amoeboid cells and with the more highly organized structure of the intestinal microvillus.

Certain unifying principles are now emerging which may ultimately allow assignment of many of these apparently different proteins to a small number of functional groups. Just as the properties of myosins have been refined by natural selection to suit the particular requirements of a given muscle, so too proteins that form gel networks of actin or regulate the dissolution of these gels may have evolved specialized properties in their individual situations yet fall within a similar functional classification. The common theme is the role of actin filaments in maintaining cell architecture and generating movement. Actin-binding proteins provide the necessary variations for the part actin has to play in such widely differing processes as egg fertilization, blood clotting, intestinal absorption and tumour invasion.

Before reviewing these actin-binding proteins, it is important to note that while the roles of actin, myosin and associated proteins in striated muscle contraction may serve as models for certain types of cytoplasmic movement, there are basic differences between these two systems which demand distinctive properties for proteins common to both. The organization of filaments in vertebrate striated muscle is highly uniform and rigidly maintained to carry out its contractile functions, but in

non-muscle systems, filamentous structures are more dynamic, responding both temporally and spatially to the cell requirements. Ca^{2+} ions serve not only to promote acto-myosin interaction, but dissolve gels and in many cases sever actin filaments. For example, recent studies have shown that α -actinin from non-muscle cells cross-links actin filaments only in the absence of Ca^{2+} ions, in contrast to α -actinin in striated and smooth muscles, which shows no comparable Ca^{2+} -sensitivity. (Indeed if it were Ca^{2+} -sensitive, disintegration of the Z-disk structure might occur during muscle activation!)

General classification of actin-binding proteins

Actin is evolutionarily highly conserved in amino acid sequence¹² which probably reflects the strong selective pressure to preserve its three-dimensional structure and thus maintain essential interaction sites for many associated proteins. Central to the role of actin is its self-association from a monomeric form (G-actin, molecular weight (M_r) 42,000) to give polymers several micrometres in length, containing about a thousand monomers. This polymerization process has been studied in detail, particularly by Oosawa and Asakura¹³ and by Wegner¹⁴ and others but is still not fully understood. The rate of filament assembly is controlled by the formation of nuclei and their production is favoured in the presence of Mg²⁺ ions. Thus, at physiological KCl concentration and with MgCl₂ in excess of 1 mM, actin exists predominantly in the polymerized form, in equilibrium with a very small (<1 µM) concentration of free monomer (the so-called critical concentration). Monomers can add to both ends of growing filaments: Pollard and Mooseker¹⁵ estimated the rates of assembly and disassembly at each end and have shown that there is preferred assembly at the 'barbed end' while preferential disassembly occurs at the 'pointed end'. (Based on the structure of actin decorated with myosin subfragment-1, these ends have been termed 'barbed' and 'pointed' by analogy with the flights on an arrow.) A consequence of any difference in assembly rates at the two ends is that actin monomers can cycle through the filaments from barbed to pointed end; this has been termed 'treadmilling'16. ATP hydrolysis is required to maintain this steady-state process. Although treadmilling of tubulin in microtubules has been clearly shown ', actin monomer exchange in vitro appears to be limited in both extent and duration at actin concentrations >10 µM¹⁷ and steady-state treadmilling has not been demonstrated to date. One consequence of a difference in assembly rates at the two ends is that filament stability is altered if one end is blocked; for example, capping the preferred assembly

0028-0836/82/170811--06\$01 00

end will cause monomer dissociation from the other end to establish a new monomer-polymer equilibrium¹⁸. I shall demonstrate below how capping proteins may affect both filament stability and polarity of assembly.

In many cell extracts, the concentration of monomeric actin is much higher than that expected on the basis of the critical concentration, due to the presence of profilins ¹⁹⁻²¹, proteins which bind specifically to G-actin and prevent polymerization. Profilins are representative of a class of proteins that stabilizes the actin monomer pool, although actin depolymerizing factors and even proteins such as DNase I may perform similar functions. (G-actin forms a 1:1 complex with DNase I and inhibits its enzymatic activity²².)

Once filaments have been formed, other proteins are needed to stabilize them in three-dimensional gels or oriented bundles. Several classes of cross-linking proteins have been described. Some of these 'gelation factors' provide cross-links insensitive to changes in Ca²⁺ ion concentration, while others operate only at Ca²⁺ concentrations $<10^{-7}$ M and the links are broken at $>10^{-6}$ M. Proteins that form actin bundles may also exist in either calcium-sensitive or calcium-insensitive forms.

Thus, these proteins act to form three-dimensional isotropic networks or tight bundles of actin filaments which themselves may further associate to produce more organized structures or to interact with membranes or cell organelles. As actin filaments are often found closely apposed to membranes, it is reasonable to suggest that specific linker proteins exist either as integral membrane components or to attach microfilaments to transmembrane elements. These have proved very difficult to identify.

Actin-containing gels can undergo contraction in conjunction with cytoplasmic myosins and suitable regulatory proteins (kinases and calmodulin). Another effect observed in the presence of Ca²⁺ ions is that of 'solation', where the gels are dispersed. Gel-sol transformations occur in some cases by severing of the actin filaments, and involve a new class of

actin-binding proteins which I term 'gelsolins'. In many cases, the severing protein remains bound to one end of the actin filament, preventing re-annealing, hence these proteins behave additionally as 'capping factors'. In this respect they mimic the effects of cytochalasin drugs, which inhibit elongation of actin filaments by binding to their barbed ends²³⁻²⁶. One possible outcome of such capping is an increased monomer concentration as a result of G-actin dissociation from the free pointed ends. In the presence of profilins, complete filament depolymerization may occur. These proteins have a second and rather different property. When added to G-actin in assembly conditions, they promote the formation of actin nuclei by binding to more than one monomer and thereby facilitate polymerization. Indeed both accelerated nuclei formation and decreased rates of elongation occur simultaneously with macrophage gelsolin in vitro (see below). Thus, depending on the conditions, these proteins may be involved in generating new filaments or in severing and disassembling pre-existing ones.

In the following sections I describe some of the proteins belonging to each of these classes, with particular emphasis on mammalian cells.

Actin cross-linking proteins—gelation and bundling

As already stated, there are several proteins which cross-link actin filaments to form either bundles or isotropic gels. In some cases, gel formation is favoured by a low molar ratio of a particular cross-linking protein to actin, while, with increasing amounts of the same cross-linker, parallel alignment of filaments occurs to form bundles. It is not possible, therefore, to designate every cross-linking protein within either the gelation or bundling subclass, but the large flexible proteins like filamin occur predominantly in gels, whereas much smaller proteins like fascin or fimbrin exist in organized actin bundles and are probably not sufficiently flexible to accommodate isotropic gel formation.

This table includes the main proteins described in the text and omits a large number of well known actin-binding proteins found in muscle and elsewhere. The molecular weights are from polyacrylamide gel electrophoresis and as buffer conditions vary between different laboratories, the values cannot be strictly compared.

* Also be should be sho

* Also a bundling protein.

Filamins. A high molecular weight actin-binding protein, purified from smooth muscle, has been termed filamin²⁷. A structurally similar protein was identified in lung macrophages²⁸ and subsequently in neutrophils, platelets and other cell types. The general morphology of macrophage actin-binding protein is indistinguishable from filamin²⁹, both appearing as two flexible strands joined at one end, but they differ in their potencies for cross-linking actin³⁰. The overall length of the dimer of $M_r \sim 500,000$ is ~ 160 nm. Here I will use the term 'filamin' for this general class of large flexible actin cross-linking proteins.

Hydrodynamic measurements indicated a native M_r of 540,000 and macrophage filamin bound to actin filaments at 40 nm intervals, giving a stoichiometry of 1 filamin per 15 actin monomers at high molar ratios³¹. Bundles of actin filaments were seen in these conditions in vitro, but at lower ratios of filamin to actin, isotropic gels were produced. The concentrations of myosin required to produce contraction of actin gels were lower in the presence of macrophage filamin than in its absence³². When actin was polymerized in the presence of macrophage filamin, branched filaments were produced having an average length less than that seen in the absence of filamin³ Filamin also accelerates the onset of polymerization and produces a perpendicular branching of actin filaments, thereby promoting the formation of an isotropic gel. It is located in the pseudopods of polymorphonuclear leukocytes during locomotion and phagocytosis³⁴, in stress fibres and membrane ruffles of dividing chick embryo cells during interphase, and appears to be concentrated in the cleavage furrow during cytokinesis³⁵.

The morphological equivalent of filamin in the red blood cell is spectrin. Although spectrin appears as a loose, flexible and elongated dimeric molecule, in contrast to filamin, spectrin dimers are joined at both ends and self-associate end-to-end to form tetramers in 0.1 M KCl. Spectrin tetramers of ~200 nm in length cross-link small protofilaments of actin (10–15 subunits long on average) to form the scaffold of proteins that maintains the shape of the erythrocyte. These complexes of spectrin and actin are stabilized by a globular protein, band 4.1 in the Steck classification³⁶. This cytoskeletal framework is attached to the membrane via ankyrin, which links the spectrin tetramers to the main transmembrane protein, band 3 (see refs 37, 38 for reviews). Spectrin-like proteins may not be restricted to red blood cells, but may serve similar functions elsewhere.

Recently, a smaller protein that gels F-actin has been isolated from *Dictyostelium discoideum*^{39,40}. Like filamin, it promotes side-to-side and end-to-side interactions between actin filaments and increases the initial rate of actin polymerization. It also seems to be localized in the cell cortex and surface ruffles. Its native molecular weight and actin-binding stoichiometry have not been characterized.

α-Actinins. While filamin and spectrin are representatives of a class of large flexible actin cross-linking proteins, a distinct class of rod-like actin-binding proteins has been identified in muscle by Ebashi and co-workers⁴¹. The archetype, α-actinin, is located in the Z-disks of muscle and seems to be involved in cross-linking actin filaments⁴². The native protein is a dimer $(2 \times M_r 105,000)$ and the molecule is highly asymmetric, with a length of 400 Å (ref. 43). α-Actinin forms gels with F-actin in vitro, although its binding to actin is inhibited by tropomyosin⁴⁴.

In non-muscle cells, antibodies to muscle α -actinin stain stress fibres and regions close to the membrane ^{4,45}. These observations suggested that α -actinin is involved in binding microfilaments to membrane surfaces. However, although immunocytochemistry shows that α -actinin is concentrated close to focal adhesion plaques in cultured cells⁴⁵, it does not form a direct link with membranes⁴⁶. Furthermore, α -actinin can be selectively dissociated from plasma membranes with little parallel release of actin⁴⁷. α -Actinin therefore seems to act as a cross-linker and spacer between actin filaments⁴⁸.

An important recent discovery is the Ca^{2+} -sensitivity of α -actinin function. Both striated and smooth muscle α -actinins cross-link actin independently of Ca^{2+} concentration, but the

 α -actinin of HeLa cells forms actin gels only at Ca²⁺ ion concentrations $<10^{-7}$ M (refs 49, 50). This calcium-sensitive cross-linking is similar to that of actinogelin from Ehrlich ascites cells⁵¹. Rod-shaped, Ca²⁺-sensitive actin cross-linking proteins have also been identified in *Dictyostelium*^{52,53}, *Acanthamoeba*⁵⁴ and blood platelets. These proteins have not been completely characterized and although they may not be related by amino acid sequence or immunological criteria, their general morphology and actin cross-linking properties suggest that they may be classified within the same group. A number of smaller gelation factors have been described in amoeboid cells such as *Dictyostelium* and *Acanthamoeba*, based on viscometric or turbidimetric measurements, but these have yet to be purified.

One further interesting property of α -actinin is that it appears to dissociate the profilin-actin complex in vitro and promote polymerization to give cross-linked filaments⁵⁵. As 1 molecule of α -actinin per 200 profilactin molecules is sufficient to cause considerable polymerization, molecules such as α -actinin may serve to mobilize actin from non-filamentous pools in cells.

Vinculin. Another protein that cross-links actin filaments is isolated originally from smooth vinculin. muscle⁴⁵ Immunofluorescence showed that it is concentrated at the termini of stress fibres near the leading edges of cells and in the region of the adhesion plaques of cultured fibroblasts, but not in surface ruffles 45,56. Because detergents are not required to solubilize vinculin, it does not seem to be an integral membrane protein. However, as it is located where microfilaments terminate close to membranes⁵⁷, it may participate in anchoring microfilaments together at specific membrane sites. In contrast to α -actinin, vinculin reduces the low-shear viscosity of F-actin solutions ^{48,50}, apparently by forming bundles of tightly packed actin filaments in a paracrystalline manner ^{48,58}. This 'bundling' role of vinculin is not universally accepted 50. Furthermore. vinculin decreases the rate of polymerization of G-actin, which again contrasts with the behaviour of α -actinins.

One feature which vinculin shares with α -actinin is the Ca²⁺-sensitivity of its interaction with actin. Vinculin isolated from muscle shows no sensitivity to Ca²⁺ ion concentration, while the protein purified from HeLa cells (in two separable forms) causes a decrease in viscosity only at Ca²⁺ concentration >1 μ M (ref. 50). More information is needed to establish the function of this protein.

Fascin and fimbrin. In 1975, Kane⁵⁹ demonstrated that isotonic extracts of sea urchin eggs formed gels at low Ca^{2+} concentrations. One protein responsible is fascin $(M_r, 58,000)$, which binds to actin to form needle-like structures composed of parallel arrays of filaments with cross-bridges at 11 nm intervals⁶⁰. This interaction is not sensitive to Ca^{2+} ions. Addition of another component of M_r 220,000 from the original gel causes aggregation of the needles into a three-dimensional network. Immunofluorescence studies show that fascin is localized in the microvillar cores which form after fertilization of the sea urchin eggs⁶¹. Thus it may be involved directly in microvillus organization and morphogenesis.

Intestinal brush border microvilli also contain proteins which stabilize the core microfilament bundles. Antibodies to one of these proteins, fimbrin, also stain membrane ruffles, microspikes and microvilli in several types of cultured cells⁶². Fimbrin binds F-actin at a saturation level of 1 fimbrin per 2-3 actin monomers, to form tightly packed bundles⁶³. In native microvilli there is a second actin cross-linking protein, villin, which will be considered in detail later. These two proteins act in a concerted manner to form filament bundles when mixed together with actin at molar ratios approximating those in isolated core bundles, that is, villin/fimbrin/actin monomers = 1:1:10.

Actin severing, capping and depolymerizing proteins

 β -Actinin and gelsolins. The earliest evidence for a protein that reduced the viscosity of actin filament solutions came from the work of Maruyama. He subsequently purified this protein,

which he called β -actinin, from a muscle extract. Gel filtration suggested a native M_r of $\sim 70,000$ and two bands of M_r 34,000 and 37,000 were obtained on SDS gels. β -actinin was shown to inhibit actin filament growth and re-annealing but to facilitate polymerization of G-actin⁶⁴. These two apparently contradictory properties will become a recurring theme (see below). Subsequently, several proteins that disrupt actin gels have been found in both mammalian and amoeboid systems.

Yin and Stossel⁶⁵ identified gelsolin, a calcium-dependent regulatory protein that solated actin-containing gel extracts from macrophage cytoplasm. Gelsolin is a globular monomeric protein of M_r 91,000, with two calcium-specific binding sites $(K_d = 9.2 \times 10^{-7} \text{ M})^{66}$. Evidence obtained from viscometry, flow birefringence and electron microscopy indicates that at low molar ratios to actin, gelsolin rapidly cleaves the actin filaments into smaller pieces⁶⁷. It was proposed on the basis of classical polymer theory⁶⁸ that this fragmentation would profoundly affect the network properties of actin. Wang and Bryan⁶⁹ described a platelet protein of M_r 90,000 which increased the rate of nuclei formation from G-actin and blocked monomer addition to the barbed ends of subfragment-1 (S-1)-decorated filaments.

Taken together, these observations suggest the existence of a severing protein which caps filament ends to prevent reannealing, but is also capable of complexing two or more actin monomers in polymerizing conditions to nucleate assembly. Recent studies with macrophage gelsolin have demonstrated very clearly this dual function ⁷⁰. Elongation of pre-formed actin nuclei in the presence of G-actin was slowed down, whereas polymerization was facilitated in the absence of such nuclei. Electron microscopy showed preferred growth from the pointed ends when gelsolin was added to S-1-decorated actin filament fragments. Thus gelsolin binds to both G- and F-actin and in both cases an increased number of shorter filaments is produced.

Several workers have reported the presence of an actin-depolymerizing factor in blood plasma⁷¹⁻⁷³. The purified protein has a molecular weight of 90,000 (refs 74, 75). Recent experiments suggest that this protein is very similar if not identical to gelsolin, in respect of its immunological cross-reactivity⁷ and its fragmentation patterns on gel electrophoresis (B. Pope, unpublished results). Furthermore, the protein behaves like gelsolin in accelerating actin polymerization in the presence of Ca2+ ions (ref. 75 and H. E. Harris and A.W., unpublished results). Increasing the concentration of plasma gelsolin (within a molar ratio to actin monomers of 1:200 to 1:50) produced filaments of decreasing length and gel electrophoresis showed most of the gelsolin sedimenting with the F-actin⁷⁵. We have shown that this protein releases depolymerized actin from filaments very rapidly and in a calcium-independent manner 77 Furthermore, a complex of the plasma protein with one or two actin monomers has been identified (H. E. Harris, unpublished results). These results cannot be reconciled within a model in which the sole action of gelsolin on actin filaments is severing, followed by capping of the barbed ends. The paradox may be reconciled partly by differences in the experimental conditions and by the fact that gelsolin binds to both G- and F-actin, but it is premature to speculate a detailed model for the function of this protein.

Fragmin and related proteins. Proteins that sever actin filaments have been isolated from several amoeboid cells. Fragmin is a protein which severs actin filaments and nucleates polymerization of monomers in a calcium-sensitive manner^{78,79}. It also forms a stable dimer with G-actin, but this has no severing activity. Tropomyosin or heavy meromyosin binding protect against fragmentation of filaments⁸⁰. A protein having similar properties has been purified from *Dictyostelium*⁸¹ and *Acanthamoeba* contains a capping protein that prevents gel formation by binding to the barbed ends of filaments, although this does not seem to have any severing activity⁸². A much smaller depolymerizing protein has been purified from brain, but its kinetics of actin disassembly are rather different from that of gelsolin⁸³.

Villin. Villin deserves special attention because it has both actin-severing and bundling activities, combining the properties of gelsolin and α -actinin. Villin is the major actin-associated protein in the core bundles of microfilaments from microvilli of intestinal epithelial cells. These microvilli are $\sim 1-2~\mu m$ long and each contains 20–30 actin filaments, held together as core bundles by villin and fimbrin. The bundles are attached to the inner membrane surface by cross-connections with a periodicity of 33 nm (see ref. 84 for review). Another protein $(M_r 110,000)^{8.5}$ forms the cross-connections to the membrane surface at 33-nm spacings, while the remaining protein component in demembranated cores is calmodulin $^{86.87}$.

Villin has two distinct properties in its interaction with F-actin. In the absence of Ca^{2+} ions ($<10^{-7}$ M), it cross-links actin filaments into bundles, but when the Ca2+ concentration is raised above 10^{-6} M, not only are the bundles dispersed, but the filaments are also fragmented. These dual properties of villin have been intensively studied ⁸⁷⁻⁹³. In addition, villin binds to actin-DNase I complexes in the presence of Ca2+ ions but is eluted from these complexes when the calcium is removed. This provides rapid purification of the protein⁸⁹. The paradox that villin does not bind to actin-DNase in the absence of calcium but bundles F-actin is not understood, but may reflect differences in its binding properties with monomeric and polymeric actin. Complexes of villin/actin/DNase (1:2:2) have been isolated by sucrose density gradient centrifugation⁸⁷. The presence of two actin monomers bound to villin suggests that it may nucleate actin filament assembly of G-actin: both villin and villin-actin complexes accelerate the rate of filament formation 90,91, the villin remaining attached to the filaments at their barbed ends90. These reactions occur only in the presence of Ca^{2+} ions (villin has one calcium-binding site, $K_d = 2.5 \times$ 10⁻⁶ M; ref 87). Addition of calcium chelators to villin-severed filaments causes re-annealing⁹², suggesting that villin capping activity is lost when calcium is removed.

Selective proteolysis by V-8 protease cleaves villin into a core fragment of M_r 90,000 and a headpiece of M_r 8,000⁹⁴. The core fragment behaves rather like gelsolin—it promotes assembly of G-actin and severs filaments, but no longer bundles F-actin 90,94. By contrast, the headpiece binds F-actin independently of Ca2+ concentration and competitively inhibits F-actin bundling by villin95. It is not clear whether bundling requires a dimer of villin, but this seems unlikely because villin does not self-associate in solution89. In addition, it is unknown how calcium ions disrupt bundling and instead cause severing and capping. If, as expected, both headpiece and core domains are involved in actin bundling, the interaction of headpiece must be modulated by Ca2+ ions. The severing mechanism is totally obscure; it could occur by direct intercalation into filaments or by weakened actin-actin interactions resulting from lateral attachment of villin to F-actin. The physiological function of the calcium-sensitive, actin-severing activity of villin is obscure, but may be related to the vesiculation of microvilli that occurs in nutritional stress and in other pathological conditions93, and a role for the large amount of calmodulin found in microvilli may be to prevent this vesiculation from occurring during normal uptake of Ca2+ ions.

The actin bundles in the microvilli extend into the terminal web, where they seem to be interconnected by fibrillar structures. In addition there are interconnections to a band of actin filaments encircling the cells close to the zonula adherens. Myosin and tropomyosin are concentrated near the rootlets of the microvillar bundles 96,97 , with tropomyosin and α -actinin being concentrated in the region of the zonula adherens 46 . The terminal web also contains a complex meshwork of 10-nm filaments which may serve to maintain rigidity of the microvilli and the adherence to adjacent epithelial cells.

Regulatory mechanisms

Table 1 summarizes information about the different classes of actin-binding proteins discussed here. It is clear that Ca²⁺ ions regulate the formation of actin bundles or gel networks in two

distinct ways. Cross-links formed by α -actinins are broken when the Ca2+ concentration rises above micromolar levels, but rapidly reform when calcium is removed. Actin gels are also disrupted in the presence of calcium by gelsolins, but in this case, removal of the calcium does not restore the gel network immediately as re-annealing of filaments occurs at a slower rate⁶⁷. In addition, Ca²⁺ ions independently regulate myosin filament formation and acto-myosin interaction via a calmodulin-dependent myosin light-chain kinase98

Calcium transients can therefore cause both contraction and solation. In some situations these phenomena may occur together, with localized disruption of gels and microfilaments sliding past one another as in muscle⁵². However, much greater contractile force may be produced if the gel network contracts without solation99. Information is now needed to establish the precise Ca2+ concentrations required for these different processes and the extent to which they are independent or synchronized.

Calcium ions also regulate the interaction of gelsolins and other capping proteins with both monomeric actin and with the ends of pre-existing filaments. The function of these capping activities in cells is unclear. Based on the behaviour of these proteins in vitro, I suggest two different properties. In conditions where steady-state treadmilling of actin may occur, capping the barbed ends of filaments would be expected to facilitate disassembly of monomers from their pointed ends 18. This could lead to complete depolymerization if the monomers were complexed with profilin or taken up by other actin filaments. Alternatively, capping proteins may function, together with free monomers, to promote actin filament formation with preferred polarity and thereby control the localization of microfilaments in cells. But how could this be achieved? One possibility is that capping factors may themselves bind to membrane proteins directly.

Actin filament growth in vivo may occur predominantly from the barbed ends¹⁰⁰. Assembly from stabilized monomer pools can be extremely rapid: the formation of the acrosomal process in Thyone sperm is the best example of this 101. How is this triggered? Current evidence suggests that a transient proton flux may initiate acrosome formation 102. The state of the nonpolymerized actin in Thyone sperm is as yet unclear, but it is likely that a profilin-like protein stabilizes the monomer pool as has been demonstrated elsewhere 19-21. In platelets it has been shown that activation by thrombin is correlated with actin filament formation¹⁰³ and this process can be inhibited by cytochalasin drugs, which also prevent the morphological changes that normally occur after platelet activation1

Our understanding of the organization and interactions of various actin-binding proteins with actin filaments in striated muscle, both during development and in active contraction, owes much to the highly organized arrangements of these proteins and their assemblies in the sarcomeres. Similar ultrastructural analysis is being carried out on the intestinal microvillus, which also is a stable and well-organized structure having relatively few components. In motile systems, however, structures like contractile rings or pseudopodia are probably too labile for X-ray analysis and may be too poorly organized for three-dimensional image reconstruction from electron micrographs. The mechanisms by which contractile elements are moved and relocated in cells, for example in cytokinesis or cytoplasmic streaming, remain a mystery: it seems probable that macromolecular structures are not moved intact, but require disassembly and reassembly. Specific organizing centres may exist, such as are known for microtubules.

Research over the past five years has identified various actinbinding proteins in a number of cell models. Here I have attempted to group these into a simple classification. Biochemical analysis is progressing rapidly, but it is important now to investigate the roles of these components in their cellular locations. One obvious approach involves microinjection 105, for example, using suitably labelled actin-binding proteins or antibodies to these components where they already exist in cells. In this way we may be able to characterize particular motile events in relation to specific proteins. If these motile events are triggered by transient fluxes of Ca2+ or other ions, then fluorescent or chromophoric reagents can be used to explore the localization and kinetics of these ion movements. In addition, the target proteins (for example, calmodulin in the case of calcium) must be identified and their subsequent activities established. One obvious regulatory mechanism involves protein phosphorylation, but direct binding by the target protein may also modulate the properties of actin-binding proteins. Knowledge of the molecular events and regulatory mechanisms involved in cell motility is a major scientific challenge and may prove of considerable medical importance.

I thank Professor J. A. Spudich and his colleagues at the Department of Structural Biology, Stanford University for much stimulating discussion during a sabbatical year. I also thank Professors K. Burridge, J. Condeelis, B. Jockusch, E. Korn, M. Mooseker, T. Pollard, T. Stossel, L. Tilney and K. Weber for providing preprints.

UV measurements of young T-Tauri stars, resembling the Sun at an age of a few million years, have recently been made with the International Ultraviolet Explorer. They indicate that young stars emit up to 10⁴ times more UV than the present Sun. The implications for the origin and evolution of O_2 and O_3 in the prebiological palaeoatmosphere are presented here. The results of photochemical calculations indicate that the O_2 surface mixing ratio was a factor 10^4 – 10^6 times greater than the standard value of 10⁻¹⁵. This new value reconciles the simultaneous existence of oxidized iron and reduced uranium.

A RELIABLE picture of the environment of the early Earth depends critically on the correct quantification of the amount of solar radiation impinging on the Earth. Standard stellar evolutionary models predict that 4,500 Myr ago, the Sun's luminosity was lower than today by $\sim 30\%$ (ref. 1). This has created the 'dim Sun paradox' because such dimming translates into a decrease of the Earth's effective temperature, T_* , of ~8%, sufficient to keep T_* below the freezing point of seawater for ~2,000 Myr (ref. 2). On the other hand, there is evidence of liquid water as early as 3,500 Myr ago², so a paradox arises. Explanations proposed to solve the problem include either increasing the greenhouse efficiency²⁻⁴ or varying the Earth's early albedo⁵. In either case, one makes inferences about the

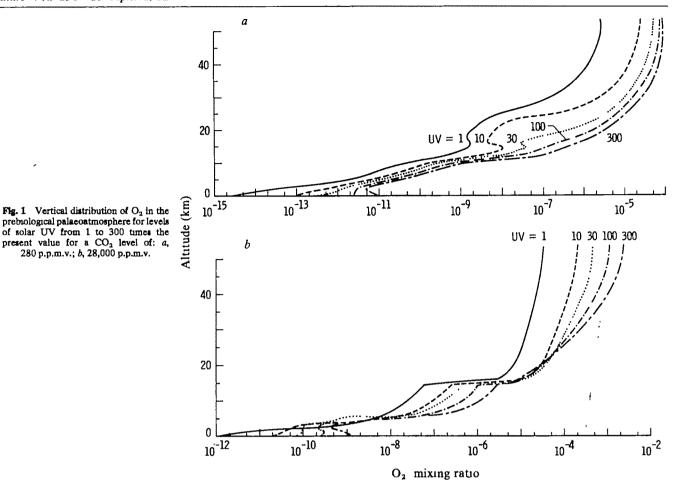

physical parameters characterizing the palaeoatmosphere using astronomical data.

We consider here another astronomical input, the UV radiation from the Sun which had a great impact on the early atmosphere of the Earth 6-12. In fact, UV radiation initiated the photochemical processes that led to the formation of oxygen (O₂) and ozone (O₃) in the prebiological palaeoatmosphere. By virtue of its strong absorption in the UV (200-300 nm), ozone protects life at the surface of the Earth from this lethal radiation. Hence, the evolution of ozone, and its variation over geological time had very important implications for the biological evolution of primitive organisms⁶⁻¹². An accurate quantification of the levels of oxygen and ozone in the prebiological

The radii of the stars have been taken as (in solar radii) 6 8, 4 7, 3.1, 8.4, 3.4, 2.6, and 3.2, respectively.

280 p.p.m.v.; b, 28,000 p.p.m.v.

palaeoatmosphere and the level of UV radiation reaching the surface of the Earth are therefore important when considering biological evolution on Earth.

The stellar evolutionary models cannot be used to predict the amount of UV generated by the young Sun and one must, therefore, rely on direct observational data. Because until recently such data were available only for the present Sun, estimates for the past UV radiation were based either on the assumption that the lower solar luminosity also implied a lower UV component or else it was assumed that the UV radiation was the same in the past as it is today⁶⁻¹².

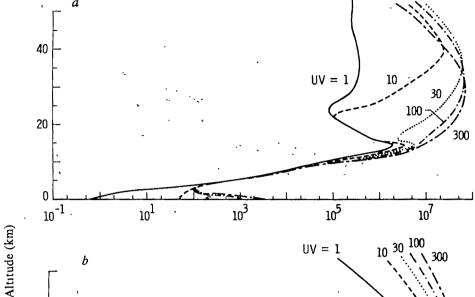

Recent observational data gathered through the International Ultraviolet Explorer (IUE) have, however, indicated that neither approach is correct. Young stars have been found to emit considerably more UV radiation than the present Sun.

The T-Tauri stars are very young stars with masses roughly equal to the Sun's. As such, they are considered to resemble the Sun at an age of a few million years. Several T-Tauri stars have recently been studied in the UV with IUE¹³⁻¹⁷. The primary result of these observations is that the stars emit strongly in the UV. Most noticeable are the chromospheric emission lines arising from the hot (10⁴-10⁵ K) atmospheres of the stars. The surface fluxes of the lines, (defined to be the flux emitted per unit stellar surface area), have been determined to be 100-5,000 times greater among the T-Tauri stars than in the Sun¹⁸. In addition, these protostars are still contracting and thus are larger than the Sun. Thus, the UV flux intercepted at the distance of the Earth is increased by an additional factor of $(R_{\star}/R_{\odot})^2$ due to the greater surface area of the protostar. We have computed the ratio of stellar-to-solar UV flux as would be measured at the Earth's distance for seven T-Tauri stars, given in Table 1. Radii for these stars were estimated from temperatures and luminosities of the stars largely taken from ref. 19. The values range from 3 to 8 solar radii and are given in Table 1. We find that the UV line flux from the T-Tauri stars is 10³-10⁴ times the present solar value.

The emission lines dominate the spectrum between 100 and 200 nm. At longer wavelengths the UV continuum of the T-Tauri stars dominates. The continuum fluxes are also enhanced by a few hundred times relative to the Sun. As we will discuss below, the wavelength intervals discussed here cover the maximum in the UV absorption cross-section of H₂O, CO₂, O_2 , and O_3 .

Young stars which are older than the T-Tauri stars continue to emit strongly in the UV, although not at the extreme levels of the T-Tauri stars. UV emission-line surface fluxes decrease with age approximately as $t^{-0.5}$ to $t^{-0.9}$ (ref. 20). The age dependent dence for the UV surface fluxes resembles that of Ca II emission, determined previously by ground-based near-UV observations²²⁻²³. We have computed the enhancement of the UV flux intercepted at the distance of the Earth as a function of age for a solar-type star, using the observational relationship reported in ref. 20 corrected for the changing radius of the contracting star. Radii at specific ages for solar mass stars were estimated from temperatures and luminosities in theoretical H-R diagrams¹⁹. The results are given in Table 2. We find that, even after the star has reached the main sequence $(5 \times 10^7 \text{ yr})$, begins

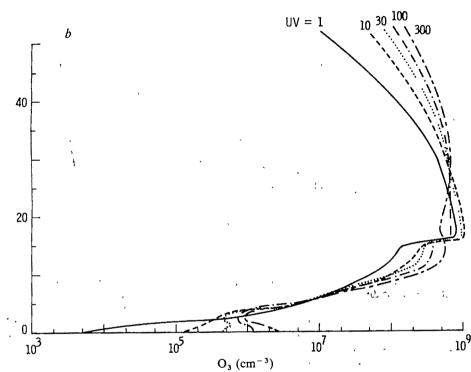

Fig. 2 Vertical distribution of O₃ in the prebiological palaeoatmosphere for levels of solar UV from 1 to 300 times the present value for a CO₂ level of: a, 280 p.p.m.v.; b, 28,000 p.p.m.v.

hydrogen burning and becomes stable, it emits about 100 times the UV radiation presently observed in the Sun.

There is no reason to believe that the youth of the Sun differed from that indicated by the T-Tauri and other young stars. We, therefore, conclude that the UV output of the young Sun was 10-1,000 times its present value. The high level of UV radiation thus indicated must have a profound effect on our understanding of the early atmosphere of the Earth.

Photochemistry of oxygen and ozone

Enhanced levels of UV radiation that may have been emitted from the Sun in its early stages may have had some very important implications for the origin and evolution of the early atmosphere, particularly for prebiological levels of oxygen (O_2) and ozone (O_3) . In the prebiological palaeoatmosphere the formation of O_2 was initiated by solar UV radiation, that is, the photolysis of water vapour (H_2O) , accompanied by the exospheric escape of atomic hydrogen (H), and the photolysis of carbon dioxide (CO_2) . The photochemical reactions governing these processes are:

$$H_2O + h\nu \rightarrow OH + H; \lambda \le 240 \text{ nm}$$
 (1)

and,

$$CO_2 + h\nu \rightarrow CO + O; \lambda \le 230 \text{ nm}$$
 (2)

^{*} See ref. 34.

Reaction (1) leads to the production of oxygen atoms (O) through:

$$OH + OH \rightarrow O + H_2O \tag{3}$$

The oxygen atoms formed in reactions (2) and (3) form molecular oxygen (O₂) through the following reactions

$$O + O + M \rightarrow O_2 + M \tag{4}$$

$$O + OH \rightarrow O_2 + H \tag{5}$$

The destruction of O_2 is controlled by its photolysis and reaction with molecular hydrogen (H_2) resulting from volcanic missions:

$$O_2 + h\nu \rightarrow O + O; \lambda \le 242 \text{ nm}$$
 (6)

and

$$2H_2 + O_2 \rightarrow 2H_2O \tag{7}$$

(See reactions (19) and (74) in Table 4.)

Closely coupled to the origin and evolution of O_3 is the origin and evolution of O_3 . O_3 is photochemically produced through the reaction:

$$O + O_2 + M \rightarrow O_3 + M \tag{8}$$

 \mathbf{O}_3 is photochemically destroyed through photolysis and reaction with $\mathbf{O}:$

$$O_3 + h\nu \to O_2 + O; \ \lambda \le 1,100 \text{ nm}$$
 (9)

and

$$O_3 + O \rightarrow O_2 \tag{10}$$

In addition, O_3 is photochemicaly destroyed by a series of catalytic cycles involving the oxiles of nitrogen $(NO + NO_2)$, hydrogen $(OH + HO_2)$, and chlome (Cl + ClO).

To study the effects of enhaned solar UV radiation on the levels of O_2 and O_3 in the prebidogical palaeoatmosphere, the photochemical model of the plaeoatmosphere of Levine et al.²⁴ was modified. This model which was originally developed to study the effect of anthropgenic perturbations on future

 $[\]dagger$ Pre-industrial level of CO $_2$ (p.p.m.v.). Other values represent multiples of this value.

levels of O₃, has been used to study the origin and evolution of O₃ for specified levels of palaeoatmospheric O₂ ranging from 10⁻⁴ of the present atmospheric level (PAL) to the present atmospheric level (1 PAL)²⁴. The model was modified such that O₂, CO₂, and H₂ which were previously specified as input parameers are now considered as chemically-active species, whose vertical profiles are calculated using coupled species continuity-flux equations, which contain both chemical production and loss terms and vertical eddy transport²⁵. The inclusion of O₂, CO₂, and H₂ as chemically-active species makes it a total of 31 species whose vertical profiles are solved simultaneously by coupled species continuity-flux equations. The other calculated speces are: O₃, O, N₂O, N, NO, NO₂, NO₃, N₂O₅, HNO₂, HNO₃, H₂O, H, OH, HO₂, H₂O₂, CH₄, CO, CH₃OOH, CH₂O, CH₃, HCC, CH₃O₂, CH₃O, Cl, ClO, HCl, CH₃Cl, and ClNO₃. Very short lived species assumed to be in instantaneous photochemical equilibrium include: O(1D), ClO2, and Cl2. The model now include 25 photochemical processes listed in Table 3, and 77 chemica reactions listed in Table 4. The US Standard Atmospheric Mid-Latitude Spring/Autumn temperature and H₂O profiles are specified in the troposphere. A primordial temperature profile that decreases linearly from the tropopause to the mesoshere is used. This profile is based on coupled photochemica-radiative equilibrium temperature calculations in the O₃-deficent palaeoatmosphere²⁶. While H₂O is specified in the tropospiere, it is calculated through the continuity-flux equation for F₂O in the stratosphere. Water soluble species, for example, INO3, H2O2, CH3OOH, HCl, ClO, and ClNO3 are lost throughout rainout, with a rainout coefficient of 1.0× 10⁻⁶ s⁻¹. The model extends from the surface up to 53.5 km with the tropopase at a height of 14.5 km. Photodissociation rates are diurnaly-averaged for a latitude of 30° and solar declination of 0°. The model includes the solar spectrum from 110 to 735 nm (ef. 27). Further details about the model are given in refs 24, 25.

For the present alculations, we have incorporated the boundary conditions for O2 and H2 given in ref. 28. O2 is considered as a chemically-active species with a zero flux lower boundary condition and H₂ hs a prescribed surface mixing ratio of 17 p.p.m.v. (ref. 28). We have studied the sensitivity of prebiological O₂ and O₃ to the level of CO₂ by performing calculations for the pre-industria CO₂ value (280 p.p.m.v.), and for 10-100 times this value. Voltile outgassing scenarios suggest that the early atmosphere may have contained as much as three orders of magnitude more CO₂ than found in the present atmosphere ^{29,30}. According to these scenarios, the bulk of the early CO2 went into the ocean and eventually formed sedimentary carbonates. The outgassed CO2 on both Mars and Venus had a very different fate-remaining in the atmospherepresumably due to the lack of liquid water and life on these planets. For our calcultions we have used five values for the flux of solar UV: the pesent value²⁷ and multiples of 10, 30, 100, and 300 times the resent value.

Oxygen and ozone in the prebiological palaeoatmosphere

O₂ profiles for the pre-industrial level of CO₂ (280 p.p.m.v.) and 100 times this value are given in Fig. 1. For each CO2 level calculations have been performed for five values of solar UV radiation ranging from 1 to 300 times the present value. The calculated O₂ profile for contemporary values of CO₂ and UV exhibits a very strong altitude dependence, with a minimum O_2 mixing ratio of $<10^{-14}$ at the surface and a maximum O_2 mixing ratio of about 2×10^{-6} above 40 km, in excellent agreement with earlier calculations²⁸. For a CO₂ value of 280 p.p.m.v. (Fig. 1), we found that increasing the UV flux from the present value to 300 times the present value resulted in increasing the surface mixing ratio of O_2 from $<10^{-14}$ to $\sim10^{-11}$. The O_2 maximum between 40 and 50 km increased from a mixing ratio of $\sim 2 \times 10^{-6}$ to 8×10^{-5} as the solar UV flux was increased by a factor of 300. For a CO₂ value of 100 times the pre-industrial value (Fig. 1b), increasing the UV flux by a factor of 300 increased the surface mixing ratio of O₂ from 10⁻¹² to 10⁻⁹. and increased the O_2 maximum at ~ 50 km from $\sim 3 \times 10^{-5}$ to $\sim 2 \times 10^{-3}$. The corresponding O₃ calculations are shown in Fig. 2a (for $CO_2 = 280$ p.p.m.) and Fig. 2b (for $CO_2 = 100$ times greater). For a CO₂ value of 280 p.p.m.v. (Fig. 2a), increasing the UV flux by a factor of 300 increased the surface concentration of O_3 from 1 to $\sim 3 \times 10^3$ cm⁻³ and increased both the height of the O_3 maximum from 14.5 to ~ 30 km and the peak concentration from 1×10^6 to $\sim 5 \times 10^7$ cm⁻³. For the enhanced value of CO₂ (Fig. 2b), increasing the UV flux by a factor of 300 increased the surface concentration of O_3 from 5×10^3 to 2×10^6 cm⁻³. For this level of CO₂ and for all values of enhanced UV radiation the height of O₃ maximum was found to be between 15 and 20 km with a concentration that varied between 5 and $10 \times 10^8 \,\mathrm{cm}^{-3}$. The total O₃ column (molecules cm⁻²) above the surface of the Earth for the O₃ profiles shown in Fig. 2 and for a CO₂ value of 10 times the pre-industrial value is summarized in Table 5.

Conclusion

Our calculation indicates that the surface mixing ratio of O₂ increased by a factor of 104-106 times the standard value of 10⁻¹⁵ (depending on the assumed value of CO₂) for enhanced level of UV radiation associated with the early Sun. Corresponding enhancement of O₃ level was also found.

These increased levels of O2 and O3 may have had important implications for early geology and on the origin and evolution of life. While the details of such implications are beyond the scope of this article, note that the higher value of O_2 found here falls within the lower (10^{-13}) and upper (10^{-3}) O_2 values arrived at to explain the simultaneous existence of oxidized iron and reduced uranium on the early Earth³¹⁻³³

Sr and Nd isotope ratios are reported for 17 mid-ocean ridge basalts and for 11 oceanic islands and island groups. Data from the Azores, Samoa and the Society Islands diverge significantly from the mantle array. These results are not explained by binary mixing of depleted and undepleted mantle reservoirs or by variable magmatic depletion of a planetary reservoir, but support mantle evolution models involving re-injection of crust material into the mantle.

ISOTOPIC studies of volcanic rocks have greatly enhanced knowledge of the chemistry and evolution of the Earth's mantle. Because of the lesser possibility of crustal contamination, much effort has focused on oceanic volcanics. In general, Sr and Nd isotope ratios in such rocks have proved to be well correlated. The establishment of this linear correlation, or 'mantle array', has been the basis of quantitative models for the present-day chemical structure and evolution of the mantle¹⁻⁴, and for estimates of the planetary ⁸⁷Sr/⁸⁶Sr and Rb/Sr ratios. New data reported here reveal that basalts from some islands have Sr and Nd isotope ratios which deviate significantly from the mantle array. These data thus raise doubts about the validity of some of these models and the estimated Rb/Sr ratio of the Earth. On the other hand, the new data generally support mantle evolution models involving significant transfer of crustal material into the mantle.

Samples from the East Pacific Rise, Mid-Atlantic Ridge, Kerguelen, Samoan Islands, Society Islands, Hawaiian Islands, Easter Island, Sala y Gomez, Guadalupe, Tristan de Cunha, Gough, St Helena and the Azores (Fig. 1) were analysed for isotopic composition of Sr and Nd at the Department of Terrestrial Magnetism, Washington; US Geological Survey, Denver; and Max-Planck-Institut (MPI) für Chemie, Mainz. Conventional mass spectrometric and chemical techniques were used except for some strontium analyses performed at MPI, which were analysed using a double collector system installed in a Finnigan-MAT 261 mass spectrometer. Replicate analysis of samples and standards confirmed that there was no systematic difference between values obtained using single collector and those obtained using double collector. The double collector mode does, however, produce better run statistics in a shorter analysis time. Some samples used in this study have previously been analysed for 87Sr/86Sr but have been reanalysed because of the higher analytical precision presently obtainable.

Most of the basalts analysed in this study are young—less than 1 Myr old—and hence the measured ratio is the initial ratio. The exceptions are basalts from Kerguelen and the Societies. No age corrections have been applied to these data as exact ages are not known in all cases. The Kerguelen samples range in age up to 27 Myr (ref. 5). In these cases, the measured ⁸⁷Sr/⁸⁶Sr ratios exceed the initial ratios by small, but significant, amounts (up to 0.00010). This difference does not affect the interpretation of the data. In the case of the Society Islands samples, which range in age up to 4 Myr (ref. 6), age corrections are not significant (equal to or less than analytical error).

Results are reported in Table 1 and Fig. 2. We first discuss the data in the context of individual localities before considering their more general implications.

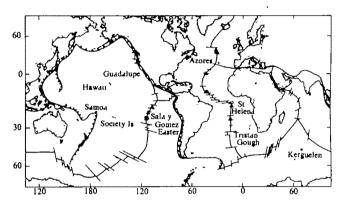

Fig. 1 Plate tectonic map of the world showing locations of dredged basalts

(▲) and islands included in this study

Kerguelen

This island was considered possibly to be a continental fragment but its oceanic nature is now firmly established^{5,7,8}. Dosso et al.^{7,8} have found that basaltic rocks from Kerguelen have ¹⁴³Nd/¹⁴⁴Nd ratios, implying source histories ranging from slight light-rare-earth depletion to significant light-rare-earth enrichment (slightly positive to significant negative ε_{Nd}). Samples analysed in this study come principally from Foch Island and Corbet Peninsular. Seven of these fall within the range of values reported by Dosso et al., but three, all from Foch Island, have significantly lower ⁸⁷Sr/⁸⁶Sr and higher ¹⁴³Nd/¹⁴⁴Nd ratios than those reported by Dosso. Kerguelen thus encompasses an enormous range of Sr and Nd isotope ratios and includes basalts with Nd isotope ratios both significantly higher and lower than bulk earth. This implies notable mantle heterogeneity on the scale of tens of kilometres. That Foch Island basalt KG5-3 has Sr and Nd isotope ratios similar to basalts from the remainder of Kerguelen but radically different from the flows immediately overlying and underlying it⁵ is further evidence of small-scale heterogeneity.

Hawaii

Sr and Nd isotopic data reported here fall entirely within the range of values reported by O'Nions et al.⁹. Our data, and those of O'Nions et al. do not reveal any systematic differences in isotopic composition between tholeiitic and alkalic lavas or systematic inter- or intra-island variations, that is while ⁸⁷Sr/⁸⁶Sr and ¹⁴³Nd/¹⁴⁴Nd ratios are quite variable in Hawaii, these variations appear to be largely random. This may, however, be due to the limited amount of data. Two apparent exceptions are (1) basalts from Molakai have notably higher ⁸⁷Sr/⁸⁶Sr than other islands and (2) the Honolulu series volcanics of Oahu have less radiogenic Sr than the Waianae series

^{*} Measured values at the Max-Planck-Institut. These values were 0.70792 and 0.51271, and 0.70808 and 0.51273 at the Department of Terrestrial Magnetism, Washington and the US Geological Survey, Denver respectively. Error quoted are 2 s.e.m. based on in-run statistics. This statistic probably slightly overestimates reproducibility, which is better evaluated from the replicate analyses. Superscripts refer to other published information of the sample.

† Sr data from ref. 22.

of that island. These distinctions do not apply to Nd. On Hawaii, the individual volcanoes are not isotopically distinct, although the Kohala lavas are notably isotopically uniform, in agreement with Feigenson *et al.*¹⁰. The easternmost and youngest volcano of the chain, Loihi, has Sr and Nd isotope ratios typical of the chain in general.

East Pacific Rise and Islands

The East Pacific Rise, Easter Island, Sala y Gomez and Guadalupe all have similar isotopic compositions which fall within the range of values from the Galapagos¹¹. The Poike and Ranu Kau basalts from Easter Island exhibit variations only slightly greater than analytical error, while EC-385 of the Terevaka volcanics has a significantly lower ⁸⁷Sr/⁸⁶Sr ratio. Previously reported ⁸⁷Sr/⁸⁶Sr ratios from Easter (summarized in ref. 12) show much more dispersion, perhaps due to the relatively large analytical error of the earlier data. Samples from the East Pacific Rise have isotopic compositions similar to other mid-ocean ridge basalts (MORB).

Mid-Atlantic Ridge and South Atlantic Islands

Except for those samples from the vicinity of 45°N, the Mid-Atlantic Ridge samples have typical MORB compositions. The 45°N area was known to be anomalous from previous stdies¹ The relatively high 87Sr/86Sr and lower 143Nd/144Nd ratios of the 45°N samples are thus not surprising. Note that the ⁸⁷Sr/⁸⁶Sr ratios of CH43 106-18 were lower after HCl leaching, indicative of seawater contamination. This may also account for the high 87Sr/86Sr ratio of CH43 106-16. Three new analyses from Tristan da Cunha fall within the range of values previously reported^{9,14}, and although there are still relatively few data from this island, it appears that the volcanics are isotopically homogeneous. Gough Island appears to be isotopically similar to but distinct from Tristan. Both Tristan and Gough have ¹⁴³Nd/¹⁴⁴Nd ratios lower than chondritic, implying timeintegrated light-rare-earth enrichment of their sources. The six St Helena samples analysed in this study suggest this island also has an isotopically uniform source but one which is quite distinct from Tristan and Gough (A. Zindler, personal communication, however, reports samples with distinctly higher ⁸⁷Sr/⁸⁶Sr). The St Helena data fall off the mantle array and are unique in that they plot to the left of it. St Helena is also unique in having extremely high ²⁰⁶Pb/²⁰⁴Pb ratios¹⁵.

Azores

Most Azores islands basalts have ⁸⁷Sr/⁸⁶Sr ratios between 0.70332 and 0.70354 but basalts from Sao Miguel can have ratios up to 0.70525 (ref. 16). Hawkesworth et al. ¹⁷ found that ⁸⁷Sr/⁸⁶Sr and ¹⁴³Nd/¹⁴⁴Nd ratios from Sao Miguel define a trend which is distinct from the mantle array. New data reported here confirm the results of Hawkesworth et al. Faial, which after Sao Miguel has the highest ⁸⁷Sr/⁸⁶Sr in the Azores, has isotopic compositions which plot at the intersection of the Sao Miguel trend and the mantle array.

Society Islands

Duncan et al.^{6,18} found that these islands become progressively older to the west, ranging in age from 1.0 to 4.3 Myr and that their Sr is highly radiogenic with ⁸⁷Sr/⁸⁶Sr ratios of 0.7036–0.7067. ⁸⁷Sr/⁸⁶Sr and ¹⁴³Nd/¹⁴⁴Nd ratios fall on the trend of the Sao Miguel data but extend it to much higher ⁸⁷Sr/⁸⁶Sr and lower ¹⁴³Nd/¹⁴⁴Nd ratios. Sample 73–185 from Tahaa, at one extreme of this trend, deviates markedly from the mantle array. There is no apparent systematic variation either in time or in space, the island of Tahaa exhibiting more variation than the other islands combined.

Samoa

Like basalts from Sao Miguel and the Society Islands, many Samoan basalts have ⁸⁷Sr/⁸⁶Sr and ¹⁴³Nd/¹⁴⁴Nd ratios which

plot off the mantle array. However, unlike Society and Sao Miguel basalts, Samoan basalts do not form a linear trend but scatter about the Sao Miguel-Society trend. Hedge et al. ¹⁹ found that ⁸⁷Sr/⁸⁶Sr ratios increased westwards along the island chain. This is borne out by the new data, which include many of the samples analysed by Hedge et al. The geographical variation is not strong, however, as, for example, Tutuila basalts plot entirely within the Upolu field.

Samoan volcanism has occurred in two phases^{20,21}: the earlier, or pre-erosional volcanism is normal island-chain type, that is becoming progressively younger to the east, but a younger episode of post-erosional volcanism has occurred along a fissure connecting the three westernmost and oldest islands. Both pre-and post-erosional volcanics have Sr and Nd isotope ratios which plot off the mantle array, and there is no apparent difference in the extent to which the two types deviate from the mantle array, although the post-erosional lavas generally have the highest ⁸⁷Sr/⁸⁶Sr and lowest ¹⁴³Nd/¹⁴⁴Nd ratios. Basalts from the Manua islands, at the eastern end of the chain, plot within the mantle array.

Contamination during or after magma ascent

Possible causes for the divergence of isotope ratios of some of the islands from the mantle array include post-eruptional weathering effects and contamination by altered basalt or sediment of the oceanic crust during magma ascent. Acid-leaching, which is useful in identifying samples affected by post-eruptional alteration (see, for example, ref. 8), reveals no difference between leached and unleached fractions (Table 1). This argues persuasively against the former possibility. Arguments against the latter have been given by Duncan and Compston¹⁸ and by Hawkesworth *et al.*¹⁷. To these may be added the following observation. The Samoan basalts tend to be primitive in nature (that is, high Mg and Ni)19, which suggests they did not spend any considerable time in a crustal magma chamber and hence are particularly unlikely to have suffered crustal contamination. Although oceanic crustal contamination during magma ascent cannot be ruled out entirely, it is unlikely to be the cause of the observed isotopic variations, which are considered to reflect chemical and isotopic heterogeneity in the mantle.

Intra-island and intra-archipelago variations

Figure 2 illustrates the variability of isotopic heterogeneity of oceanic islands. Single isolated islands such as St Helena, Tristan da Cuhna, Ascension and Bouvet (Table 1 and ref. 9) tend to

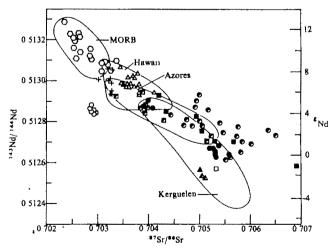

Fig. 2 Results obtained in this study plotted on a ⁸⁷Sr/⁸⁶Sr versus ¹⁴³Nd/¹⁴⁴Nd variation diagram. Fields for mid-ocean-ridge basalts (MORB), Azores, Hawaii and Kerguelen are drawn on the basis of these and previously published data ○, MORB; +, Easter Island and Sala y Gomez; *, Guadalupe; △, Hawaii, ○, St Helena; El, Azores, ●, Samoa, Societies, □, Gough, △, Tristan da Cunha, and ♠, Kerguelen Much of the data from Samoa fall outside the boundary of the conventional mantle array and data from Sao Miguel (Azores) and the Societies define a trend at low angle to the mantle array.

be isotopically homogeneous while islands or island groups associated with large oceanic plateaus, such as Iceland, Kerguelen, Hawaii, the Galapagos and the Azores (Table 1 and refs 8, 9, 11, 17, 22, 23), exhibit more variation, as do the Pacific island chains, such as Hawaii, Samoa and the Societies.

However, the apparent homogeneity of some islands may be related to sampling problems, and the question of local isotopic variations on oceanic islands requires a much more systematic approach to sampling than has previously been undertaken.

These intra-island and intra-archipelago variations may result partially or largely from mixing of an enriched source (or a melt derived from such a source) with depleted mantle. The apparent homogeneity of some islands indicates that such mixing is not ubiquitous. Furthermore, in the case of Samoa, Sr-Nd and particularly Sr-Pb relationships²⁴ suggest heterogeneity of the source is due at least in part to factors other than mixing with depleted mantle.

Mantle evolution

Explanations for the Nd-Sr relationship which have been suggested include mixing between a primitive or planetary reservoir having $^{87}\mathrm{Sr}/^{86}\mathrm{Sr}$ of $\sim\!0.705$ and $^{143}\mathrm{Nd}/^{144}\mathrm{Nd}$ of $\sim\!0.51265$ and a depleted reservoir with the isotopic characteristics of MORB (that is $^{87}\mathrm{Sr}/^{86}\mathrm{Sr}=0.7027$ and $^{143}\mathrm{Nd}/^{144}\mathrm{Nd}=0.51315)$ and variable depletion of an initially homogeneous planetary reservoir, the most severely depleted portion represented by the MORB reservoir $^{2-4}$. A basic assumption of these models is that the relationship between Sr and Nd isotopic ratios in oceanic basalts is monotonic. That the $^{87}\mathrm{Sr}/^{86}\mathrm{Sr}$ ratio of the bulk earth may be found by taking the intersection of the 'mantle array' with the chondritic $^{143}\mathrm{Nd}/^{144}\mathrm{Nd}$ is implicit.

The new data presented here and those of Hawkesworth et al. 17 clearly violate the assumption of a single linear relationship describing Nd and Sr isotopic variations in oceanic basalts. We thus have to choose whether to retain the established assumptions and explain the new data as deviations from the rule, or to suspend the assumption of the linear nature of the data and

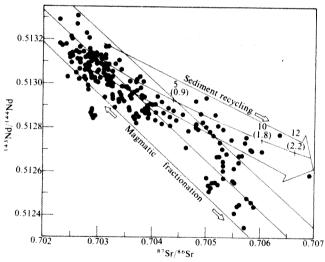

Fig. 3 Variation of ¹⁴³Nd/¹⁴⁴Nd with ⁸⁷Sr/⁸⁶Sr in oceanic basalts. The data clearly define a wedge-shape rather than linear array. One possible explanation is illustrated: magmatic fractionation of Rb/Sr and Sm/Nd (perhaps principally that occurring at mid-ocean-ridges, as suggested in refs 33–35) in time results in a linear band of data while injection of continent-derived sediment into the mantle results in deviation from this linear pattern. Also shown is the effect of mixing a hypothetical ancient oceanic sediment (Rb/Sr and Sm/Nd identical to the deep-sea red clay analysed by McCulloch and Wasserburg³⁷ but having a model age of 2,000 Myr, that is present ⁸⁷Sr/⁸⁶Sr = 0.7239 and ¹⁴³Nd/¹⁴⁴Nd = 0.51204) with a reservoir having the isotopic composition of MORB. This sediment would be roughly appropriate with a 1,800 Myr recycling time for example, refs 35, 36. Ticks and numbers along the mixing line refer to the per cent sediment in the mixture. Numbers in parentheses refer to the case where the depleted end member is mantle with 20 p.p.m. Sr, those without parentheses to mixing with basalt having 120 p.p.m. Sr. Sources of data: Table 1, refs 8, 9, 17, 11, 23, 47–51 and W.M.W (unpublished).

accept the new data into the mantle array without special pleading. If we take the latter course, the mantle array becomes a rather broad band of data where several subsets (from individual island groups) have trends with substantially different slopes. In that case, the assumption of a basically binary system cannot be maintained, and we cannot make any quantitative estimates about a point representing bulk earth. For example, it is quite reasonable to think that the Earth has differentiated to produce six geochemically distinct reservoirs: (1) an upper continental crust; (2) a lower continental crust, (3) an oceanic crust; (4) a depleted mantle region; (5) an undepleted mantle region; and (6) the core. The conventional linear mantle array might then be produced by mixing of (4) and (5), (3) and (4), or perhaps even (1) and (4). The different trends within the mantle array may then be the result of different combinations, but there is no requirement that the bulk earth point must lie within the array. Similar arguments can be made for Pb isotopes, which, on the ²⁰⁷Pb/²⁰⁴Pb versus ²⁰⁶Pb/²⁰⁴Pb diagram, show an overall positive correlation. These can be resolved into several different individual subparallel trends for individual island groups, but virtually all the data lie outside the locus of possible values of bulk earth Pb isotope ratios.

The data from Sao Miguel, Samoa and the Societies are offset from the conventional mantle array in the direction of continental crust and in this sense, the involvement of some kind of crustal component is implied, as Hawesworth et al. 17 suggested with reference to Sao Miguel. If this crustal component is not added during ascent of the magma, then it must be present in the source. The possibility of transport of crustal material into the mantle, suggested by Armstrong²⁵, has recently received wide consideration (see refs 1, 26-36), and Hofmann and White^{34,35} and Chase³⁶ have specifically proposed that recycled oceanic crust is the source of oceanic island basalts. An interpretation of the Sr and Nd isotope data consistent with recycling of oceanic crust is shown in Fig. 3. Magmatic processes operating during the formation of oceanic lithosphere produce correlated variations in Rb/Sr and Sm/Nd. Most of this lithosphere is ultimately returned to the deeper mantle and in time, correlated variations in ⁸⁷Sr/⁸⁶Sr and ¹⁴³Nd/¹⁴⁴Nd result which define the conventional linear mantle array³³⁻³⁵. Addition (and subduction) of continent derived sediment or seawater interaction with crust will, however, produce deviations to the right of the mantle array. The effect of mixing between a hypothetical 'ancient' oceanic sediment and a MORB-type composition is illustrated. As Fig. 3 shows, such mixing can at least qualitatively account for those sources with compositions outside the conventional mantle array and that relatively small amounts of sediment are required. In this interpretation, whether a particular unit of recycled crust has compositions lying outside or inside the conventional mantle array depends on the extent to which the crust has interacted with seawater and/or the extent to which associated sediments are subducted. Sources lying inside the conventional mantle array, such as Tristan and Kerguelen, may represent recycled crust with little or no subducted sediment.

The mixing curve shown in Fig. 3 is illustrative only. The range of isotopic compositions in modern oceanic sediments, much less ancient ones, is not well known; thus any attempt at more quantitative modelling is not justified. It is clear, however, that sediments can be highly variable^{37,38}, both in isotopic composition and in Rb/Sr, Sm/Nd and Sr/Nd ratios (the latter determining the curvature of mixing curves). Even compositions lying inside the conventional mantle array, for example Tristan and Kerguelen, could be explained by mixing between a sediment, for example the North American Shale Composite³⁷, and depleted mantle.

Seawater is also a possible 'continental contaminant', as mentioned above. Sediment has been emphasized here because of the correlated variations in Sr and Nd isotope ratios in the Society Islands and Sao Miguel trends seem to suggest a contaminant containing both Sr and Nd, whereas seawater, which contains essentially no Nd, would be expected to affect only

the Sr isotope ratios. On the other hand, the correlation between Sr and Nd isotope ratios in the Samoan source is weak, which might indicate that seawater is the contaminant.

It is also possible that reservoirs having isotope ratios lying outside the mantle array result from purely magmatic processes. Diagrams illustrating the effects of partial melting on Rb/Sr and Sm/Nd ratios (for example Fig. 5 of ref. 9; Fig. 4 of ref. 17) reveal that these sources could be produced as partial melts of a previously depleted mantle. This possibility is also consistent with recycling of oceanic crust as partial melting of a previously depleted reservoir occurs during MORB genesis.

Models involving recycling of oceanic crust thus provide several possible means of explaining both those data falling outside the conventional mantle array and those sources having ¹⁴³Nd/¹⁴⁴Nd ratios lower than bulk earth. Neither of these features are consistent with binary mixing between a depleted and an undepleted reservoir, such as advocated by Wasserburg and DePaolo³, or with variable depletion of a primordial reservoir4.

Conclusions

In view of the above new data, as well as those of Hawkesworth et al.¹⁷, recycling of oceanic crust into the mantle deserves serious consideration as an important process in the chemical

evolution of the Earth. However, Pb, Hf, He, Ar as well as Sr and Nd isotopic data, chemical data and geophysical and chemical plausibility must be carefully considered before such models are accepted. The present data support such models rather than confirm them. On the other hand, these new data cannot be explained in terms of simple mixing between an undepleted planetary mantle reservoir and a depleted one, nor can Pb isotope data. Such an undepleted reservoir, though it may exist, must have only a very minor role in present crustmantle interaction. The data are also not explained solely by variable magmatic depletion of an initially homogeneous mantle.

Finally, until the complexities of Sr-Nd isotope systematics in the mantle are better understood, values of 87Sr/86Sr and Rb/Sr for the bulk earth estimated from Sr-Nd relationships in oceanic basalts must be viewed with scepticism.

Kinematics of oceanic thrusting and subduction from basal sections of ophiolites

F. Boudier, A. Nicolas & J. L. Bouchez

Laboratoire de Tectonophysique, Université de Nantes, rue de la Houssinière, 44072 Nantes Cedex, France

The structural analysis of high stress deformation at the base of the peridotite section in many ophiolites in suture zones enables the kinematics of oceanic convergence responsible for the suture to be defined. This deformation results from the thrusting over oceanic crust of a young lithosphere involved in a subduction process. Flow plane, flow line, sense of shear related to the thrusting are geometrically deduced from the study of mineral preferred orientations in the basal peridotite and in the quartzites belonging to the amphibolite sole.

In the palinpsestic reconstruction of palaeotectonics, a key problem is to determine kinematics of plates (direction and sense of relative motion) at destructive margins. At present, the following information is available.

First, the direction of the palaeo suture zone is assumed to be parallel to the trend of ophiolite and blueschist lineaments and to the alignment of eruptive bodies which are ascribed to an active margin magmatism. However, no information is available on the direction of motion of the subducting plate. This direction may be nearly parallel to the suture direction as is the case along the western boundary of the Pacific plate¹ and along the eastern segment of the Hellenic trench system²

Second, the sense of the palaeo subduction is deduced from: (1) the different geological characters between the active and

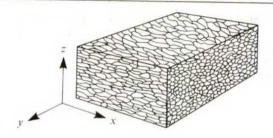

Fig. 1 x, y, z axes of the finite strain defined from the shape fabric: foliation (xy plane) and mineral lineation (x direction).

passive margins of the suture. The active margin is characterized by arc sedimentation, andesitic—granodioritic magmatism, and K/Na polarity, whereas the passive margin is characterized by a sedimentation of continental rise type. Such a simple scheme may be obscured by complex collision situations. (2) The sense of thrusting of the ophiolites which is inferred from their position with regard to the former oceanic crust from which they derived. This criterion is still ambiguous as obduction has been related to either sense of subduction³⁻⁵. Moreover it is not always possible to recognize a thrust whose kinematics is connected to the subduction process from one due to later nappe emplacement, possibly driven by gravity.

A new approach to this problem is now proposed, based on the study of basal tectonites and metamorphic aureoles of many ophiolites. These formations have been ascribed to oceanic thrusts⁶⁻⁸. Kinematic analysis of deformation mainly in the peridotite mylonites makes it possible to deduce the direction and sense of transport of the upthrust lithosphere which may then be related to the direction of convergence of the plates.

Large homogeneous deformations

The kinematic analysis of homogeneous plastic deformation has recently been developed, in particular in peridotites^{9,10} and in quartzites¹¹.

In rocks deformed by homogeneous plastic flow, we accept the concept that the principal axes of the finite strain ellipsoid $x \ge y \ge z$ coincide with the principal axes of the shape anisotropy of minerals, with z perpendicular to the foliation and x parallel to the mineral lineation (Fig. 1). In peridotites, the principal directions of strain are marked by the shape of the olivine crystals, or better, in the field, by spinel or feldspar aggregates. In quartzites they are marked by the shape of quartz crystals, often emphasized by phyllitic bands.

Fabric measurements in peridotites and quartzites show that the mean orientation of slip directions and slip planes in the principal minerals (olivine and quartz respectively) are related to the axes (x, y, z) (Fig. 1) of the finite strain ellipsoid so that the mean direction of slip commonly lies at small angle to the x axis (Fig. 2a). This obliquity has been observed in numerous cases and in various materials; it has been attributed to shear flow (see refs 10, 12), with the inference that the flow plane and the flow line can be equated with the mean orientation of the slip planes and the slip lines respectively in the principal rock-forming minerals (Fig. 2b). The sense of shear flow is deduced from the sense of the obliquity. This interpretation has been confirmed by planar simulation of simple shear 13 , by studies in natural shear zones where the flow geometry is well known $^{14-16}$ and recently by experimental deformation in ice 17 .

The obliquity of the kinematic directions relative to the x and z axes of the finite strain ellipsoid can be deduced from petrofabric measurements (Fig. 2b), or more simply from thin sections cut parallel to the xz plane observed between crossed polarizers (Fig. 2a).

Oceanic thrusting conditions

The basal peridotites in many ophiolite complexes (see refs 7, 18) overlie a sole of metamorphic rocks with facies grading downwards from granulite and/or amphibolite facies to greenschist facies. This metamorphism is developed in oceanic crust formations as a result of mechanical and thermal effect of an overriding slice of oceanic lithosphere 6.7.19. Thirty ophiolite

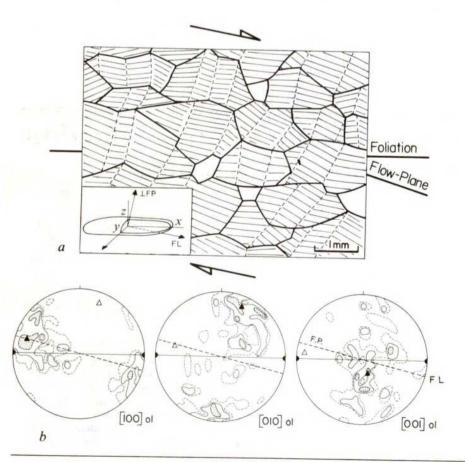

Fig. 2 Schematic section in the xz plane of an olivine or quartz aggregate. Dashed lines are the traces of sub-boundaries (visible under crossed polarizers), perpendicular to the slip direction. Solid lines are the traces of slip planes (not directly visible under crossed polarizers). The sense of shear is deduced from the orientation of foliation relative to average slip plane (equated to the flow plane, FP) and/or lineation relative to average slip direction (equated to the flow line, FL). b, Equal area projection (lower hemisphere) of the olivine crystallographic axes. The flow plane (FP) (dashed line) is equated with the average slip plane (010)ol, the flow line (FL), with the average slip direction 100_{ol}. massifs are known which present such a metamorphic sole¹⁸. The following description relies on structural studies conducted in six massifs and especially in the Bay of Island (Newfoundland)²⁰ and Samail (Oman)²¹.

Above the contact with the amphibolites and within a few hundred metres of it, the peridotites of the ophiolite suite

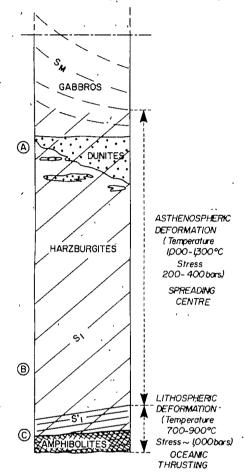

Fig. 3 a, Schematic cross-section through the lower part of an ophiolite sequence showing structures of the lithospheric deformation (S_1') superimposed on that of the asthenospheric deformation (S_1) . S_M is the cumulate layering. A, hypersolidus asthenospheric deformation; B, subsolidus asthenospheric deformation; C, lithospheric deformation. These zones refer to the models in Fig. 5.

exhibit mylonitic textures indicative of large strain-high stress deformation (Fig. 3). According to the olivine neoblast size piezometry, the stress is evaluated at 1-2 kbar (ref. 18). The temperature in these peridotites is estimated at 700-900 °C if they are considered to be in thermal equilibrium with the underlying amphibolites and granulites. This deformation is clearly distinct from the high temperature-low stress one (Fig. 3) which affected the whole ultramafic sequence and originated from the asthenospheric flow in a spreading environment. Temperatures during the asthenospheric flow are close to the peridotite solidus (1,250 °C) and stress is of the order of 200-300 bar (ref. 18).

The amphibolites underlying the peridotites often contain intensely deformed quartzite bands deriving from the silica-rich oceanic sediments. These rocks may have recorded several superimposed tectonic events corresponding to decreasing temperatures²². The highest temperature deformation, contemporaneous with the contact metamorphism, is ascribed to the oceanic thrusting. It produces a penetrative foliation and a lineation which are parallel with those in the overlying peridotites. The kinematic analysis of the thrusting can equally well be undertaken in the mylonitic peridotites or in the quartzite bands from the amphibolites. However, the low temperature limit for plastic deformation of quartz may mean that quartzites also recorded later events such as nappe emplacement.

Kinematics of oceanic thrusting

The proposed method has already been applied in the study of the Bay of Island ophiolite in Newfoundland²⁰ and of the Samail ophiolite in Oman²¹.

Figure 4 illustrates the case of the case of the Samail ophiolite. The high stress deformation traced at the very base of the peridotite has the same geometry as the deformation recorded in the amphibolites; it contrasts with the low stress—high temperature deformation producing coarse porphyroclastic textures in the main part of the peridotite sequence. Lattice preferred orientations of orthopyroxene (Fig. 4a) in mylonitic peridotite and of quartz (Fig. 4b) in quartzites display an obliquity to the penetrative foliation and lineation which indicate the same sense of shear for both rock types.

In geodynamic situations, two possible decoupling surfaces are envisaged (Fig. 5), in which thrusting of young oceanic crust could be initiated, due to oceanic convergence.

First, at a spreading axis itself²³, if there is a shift from oceanic expansion to convergence. The compressive force may initiate thrusting along the lithosphere—asthenosphere interface (Fig. 5a). The decoupling surface would correspond to the isotherm representing the lower limit for peridotite high temperature

elastic stresses are located at shallow depth along a roughly horizontal decoupling surface.

In the first case, the thrusting will predate the establishment of a subduction process, as it is related with the initiation of the convergence process. In the second case the thrusting may postdate an active subduction, occurring at the time when young crust is involved in the subduction process.

Enzymatic synthesis of bacteriophage fd viral DNA

Thomas F. Meyer & Klaus Geider

Max-Planck-Institut fur medizinische Forschung, Abteilung Molekulare Biologie, Jahnstrasse 29, D 6900 Heidelberg, FRG

An enzyme system with requirements similar to those for replication of phage fd replicative form (RF) DNA in bacteriophage fd-infected cells has been reconstituted with purified fd gene 2 protein, and DNA polymerase III holoenzyme, DNA binding protein I and rep-protein (rep-helicase) of Escherichia coli. The system generates viral circular single strands, which are infective for E. coli spheroplasts. Parental and newly synthesized DNA are covalently connected in early stages of replication, as expected for DNA replication using the rolling circle mechanism. Single-stranded tails of the rolling circle intermediates are cleaved after a full round of replication by gene 2 protein and circularized by the same enzyme molecule.

THE F-pili specific filamentous bacteriophage fd, which is closely related to phages M13 and f1, has been extremely useful in the study of structural and functional aspects of small viral DNA genomes. The organization of the circular fd genome and its nucleotide sequence have been analysed in detail, and the single-stranded character of fd DNA has given rise to the construction of unique vector systems for cloning and quick sequencing of genes1.

The life cycle of bacteriophage fd² begins with the entry of the viral DNA into an Escherichia coli cell, where it is immediately converted into a double-stranded replicative form. RF replication then occurs, forming a pool of double-stranded DNA molecules. RF replication requires the phage-encoded gene 2 protein as the sole enzyme function encoded by the phage³. In a late stage of infection the pool of RF molecules

is used as a matrix for the production of new viral single strands.

On the basis of genetic data, host functions of Escherichia coli essential for replication of filamentous phages have been assigned to DNA polymerase III and I4, RNA polymerase, DNA gyrase and probably DNA binding protein I⁵. The involvement of E. coli RNA polymerase and DNA gyrase has been deduced from the inhibition of phage replication by the drugs rifampicin⁶ and nalidixic acid⁷. Rifampicin specifically interferes with the synthesis of the complementary strand in the stage of duplex propagation8, whereas nalidixic acid affects RF replication, but not the conversion of single strands to RF⁷. Another E. coli gene function involved in RF replication of small bacteriophages is encoded by the rep gene⁹. Participation of the dnaB and dnaG gene products has also been proposed for replication of filamentous phages^{10,11}, although their requirement in enzymatic replication of fd RF has not been demonstrated.

Enzymatic studies have revealed the participation of the *E. coli* proteins DNA binding protein I, RNA polymerase, DNA polymerase III holoenzyme, DNA polymerase I and DNA ligase in the conversion of single strands to RF¹². The polymerases are required, respectively, for synthesis of the RNA primer, elongation of the DNA chain and excision of the primer concomitant with gap filling¹³. The DNA binding protein directs the initiation event and supports DNA polymerase III in DNA replication. DNA ligase seals the double-stranded DNA into the relaxed circular covalently closed form (RFIV).

To initiate double-strand replication, the relaxed RF is converted into supercoiled RFI by DNA gyrase. Phage fd gene 2

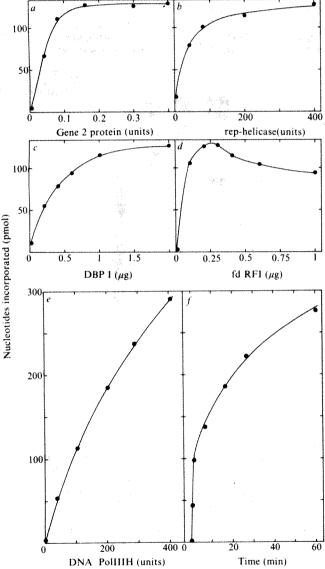

Fig. 1 Proteins required for enzymatic replication of fd RF. The standard incubation mixture contained 200 ng fd RFI (600 pmol of nucleotides), 0.08 U of fd gene 2 protein, 100 U of E. coli rep-helicase, 1 μg E. coli DNA binding protein I, 100 U of E. coli DNA polymerase III holoenzyme in 20 μl of 20% sorbitol, 50 mM HEPES (pH 7.5), 0.1 mg ml⁻¹ bovine serum albumin, 5 mM 2-mercaptoethanol, 5 mM MgCl₂, 500 μM ATP, 50 μM of dATP, dGTP and dTTP, and 25 μM of ³H- or ³²P-labelled dCTP (1,000–3,000 c.p.m. pmol⁻¹). Incubation was for 5 min at 30 °C. The nucleotide incorporation was stopped with 5% perchloric acid and the acid-insoluble radioactivity determined. The sources of the proteins have been described elsewhere ¹⁷. a, fd gene 2 protein; b, E. coli rep-helicase; c, E. coli DNA binding protein I; d, phage fd RFI; e, E. coli DNA polymerase III holoenzyme. f Gives the time course of nucleotide incorporation.

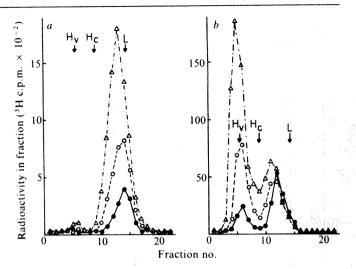

Fig. 2 Analysis of bromouracil-labelled replication products in alkaline caesium sulphate. In the standard incubation mixture, dTTP was replaced by bromodeoxyuridine triphosphate. Incubation was stopped at various times by the addition of 80 μl of 0.1 M NaOH and 10 mM EDTA. The Cs₂SO₄ gradients were run in a Beckman 50 Ti fixed-angle rotor at 40,000 r.p.m. and at a mean density of 1.46 g ml⁻¹ for 28 h at 20 °C in 0.08 M NaOH/10 mM EDTA. Increasing density is from right to left. Panel a: ●, 15 s; ○, 30 s; △, 60 s. Panel b: ●, 2 min; ○, 4 min; △, 8 min of incorporation. External markers were bromodeoxyuridine-substituted fd viral strands (H_v) and complementary strands (H_c) and fd single-stranded DNA of light density (L).

protein cleaves this DNA in the viral strand¹⁴ at a specific site^{15,16}. Gene 2 protein supports strand unwinding by rephelicase (rep-protein)¹⁷ and the 3'-hydroxy end of the viral strand is extended by DNA polymerase III holoenzyme. Both reactions require the presence of E. coli DNA binding protein I. Cleavage and circularization of replicated viral strands by fd gene 2 protein have been demonstrated in model systems^{18,19}. In addition, replication of duplex DNA from filamentous phages has been reported for a subcellular E. coli system²⁰.

Information on the mechanism of DNA replication has been obtained with Φ X174 DNA for the conversion of viral strands into supercoiled duplex DNA²¹, and its simultaneous replication into viral and complementary strands²². Although this system is structurally related to the phage fd replication system, it differs substantially regarding enzymatic requirements and the mode of action of the enzymes involved^{13,23}. Replication systems using linear double-stranded DNA as a substrate, that is, the T4²⁴ and the T7²⁵ in vitro systems, have given insight into the mechanistic principles of a replication fork.

Here, we analyse an enzyme system for replication of doublestranded fd DNA which is assembled with proteins present in the fd-infected cell. We will discuss in detail the mode of action of gene 2 protein as the key enzyme in the production of circular bacteriophage fd viral strands.

Enzymatic requirements for replication of fd RFI

In accordance with the requirements for phage fd replication in vivo, an enzymatic system was set up for components stimulating DNA synthesis on supercoiled fd RFI DNA. The influence of the individual proteins—fd gene 2 protein, E. coli rep-helicase, E. coli DNA binding protein I and E. coli DNA polymerase III holoenzyme—and of the template DNA fd RFI on the incorporation of deoxyribonucleotides is shown in Fig. 1. The DNA and the replication proteins can be added up to saturating amounts in standard incubation conditions, except that increasing amounts of DNA polymerase III holoenzyme do not reach a plateau of nucleotide incorporation (Fig. 1e). DNA synthesis starts immediately after incubating the assay mixture at 30 °C, decreases slightly after 5 min of incubation,

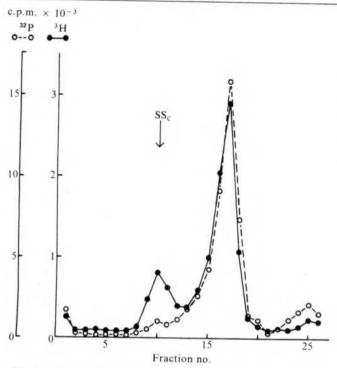

Fig. 3 Gradient analysis of replication products. a, Sedimentation in neutral sucrose. The template $^3\text{H-fd}$ RFI (10,000 c.p.m.,300 ng) was isolated from phage-infected cells. A volume of $60\,\mu\text{l}$ (three times the assay system described in Fig. 1 legend) with label in $[\alpha^{-3^2}\text{P}]\text{dCTP}$ $(1,700\text{ c.p.m. pmol}^{-1})$ was incubated for 5 min at 30 °C. After the reaction had been stopped with NaCl/EDTA, the sample was diluted with $100\,\mu\text{l}$ of 1 M NaCl in Tris-HCl/EDTA and layered on top of a neutral sucrose step gradient. Sedimentation was performed in a Beckman SW60 Ti rotor for 2.5 h at 50,000 r.p.m. and $20\,^{\circ}\text{C}$. To fractionate the gradient the tubes were punctured in the bottom. Sedimentation is from right to left. The position of fd circular single strands (SS_C) as external marker is indicated.

and is still occurring at $60 \, \text{min}$ (Fig. 1f). At that time, the amount of nucleotides incorporated approaches the equivalent of one round of viral strand synthesized per RF molecule.

Products generated in the replication system

To determine the mode of replication implemented in the enzyme system, density label was incorporated into newly synthesized DNA via substitution of thymidine triphosphate by bromodeoxyuridine triphosphate. Subsequent equilibrium sedimentation analysis of the replicated DNA in denaturing conditions reveals label in two distinct positions: at heavy density, corresponding to heavy viral marker DNA, and at intermediate-light density (Fig. 2). The latter material, which is predominantly found at early incubation times, indicates a covalent connection of heavy newly synthesized and light parental DNA. These results support the rolling circle model for fd double-strand replication which implies synthesis of the viral strand by covalent elongation of the parental viral DNA. The tail of single-stranded DNA generated in this reaction is then cleaved off late in the replicative cycle. Heavy material in the density gradient represents this kind of processed viral DNA which is found after ~60 s of incubation.

To monitor the production of fd single strands, ³H-labelled fd RFI was used as template and newly synthesized material was labelled with ³²P-dCTP. Sedimentation of the products in neutral sucrose separated single-stranded from double-stranded DNA (Fig. 3). Quantitative evaluation of the distribution of both labels revealed that 25% of the total radioactivity of the template occurred as single-stranded DNA. About 6% of the newly synthesized ³²P label sedimented in the position of single-stranded material. These results show that half of the template molecules were replicated and the single strands with

parental label were cleaved from the double-stranded core, but label from the second round of replication could not be detected efficiently by sedimentation in neutral sucrose.

We have further investigated the replication products by electrophoresis in agarose gels, where linear and circular single strands can be separated from each other. Figure 4a shows that the single-stranded newly synthesized DNA migrated in the position of circles, whereas linear single strands of unit length were less than 1% of the circular DNA. This result illustrates the efficient circularization of single-stranded DNA by gene 2 protein in the E. coli replication system. Because no label is incorporated into single strands in the first round of replication, these circles are derived from following rounds of viral strand synthesis.

The production of circular fd single strands was shown by migration with regard to single-stranded marker DNA (Fig. 4a), but also proven by conversion of the material into double-stranded DNA (Fig. 4b, c). The enzymatically synthesized single-stranded DNA was nonspecifically primed with plasmidencoded DNA primase²⁶, the RNA primer was extended with

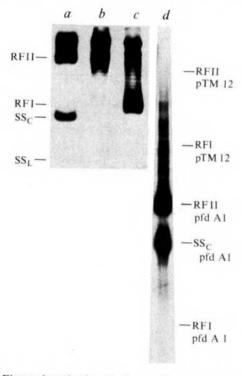

Fig. 4 Electrophoresis of replication products on agarose. a, A standard incubation mixture (see Fig. 1) with $[\alpha$ -(720 c.p.m. pmol-1) was stopped with SDS buffer and the DNA separated on a 1% agarose gel. b, Incubation was as in a but without label. The mixture was then heated to 65 °C for 5 min and incubated after addition of $[\alpha^{-32}P]$ dCTP with DNA primase encoded by the I-like plasmid R64drd11 (from E. Lanka) coli DNA polymerase I (0.1 µg) and T4 DNA ligase (2 µg)³ for 1 h at 20 °C. c, The products of b were incubated with 2 units of purified DNA gyrase 17 for 30 min at 30 °C. External markers were single-stranded circular fd DNA (SSC) isolated from the purified phage, linear single-stranded fd DNA (SSL) obtained by cleavage of fd single-stranded circles with pancreatic DNase; fd RFI (RFI) isolated from fd-infected cells; fd RFIIo (RFII) generated by cleavage of RFI with fd gene 2 protein and linear single strands (RFIII), obtained by cleavage of fd RFI with gene 2 protein in the presence of Mn²⁺ (ref. 14). d, Replication of plasmid pfdA1 (2.4 kb)³. The plasmid (200 ng), which contains a cloned 261-base pair origin fragment of phage fd, was replicated in conditions described in Fig. 1 legend. In addition, 50 ng of the pBR derivative pTM12 (6.2 kb)³, bearing the gene 2 of fd but not the fd origin, were present in the assay and served as an internal control for the specificity of the replication system. The products were separated by electrophoresis through 1.5% agarose. The singlestranded nature of the pfdA1 replication product, SSc, was controlled by digestion with S1 nuclease.

Table 1 Gene 2 protein-mediated activation of fd RF replication

	DNA syr the four-c system	omponent	Product of first
Substrate	-G2P	+G2P	round of replication
fd RFI	5	120	SS circles
fd RFIV	6	3	444444
fd RFII _o	18	· 84	SS circles
fd RFII	14	103	SS linear DNA of unit length
fd RFII	16	15	anaman .

The template DNA (200 µg) was added to the standard assay system (see Fig. 1). Products were analysed by agarose gel electrophoresis and subsequent quantification of unlabelled (first round of replication) and labelled (following rounds of replication) single-stranded (SS) DNA species. The analysis was accompanied by electron microscopic evaluation 17. G2P, gene 2 protein; fd RFII_o, phage fd replicative form DNA specifically cleaved with fd gene 2 protein; RFII_p represents RFII_o without 5'-phosphate on the cleaved viral strand.

DNA polymerase I and the strands were finally sealed with T4 DNA ligase (Fig. 4b). Subsequent treatment of this DNA with gyrase should shift all closed circular molecules into the position of supercoils in the gel. This indeed can be observed in Fig. 4c, proving the circular nature of the originally synthesized single strands. Control experiments in the absence of primase showed that an excess of T4 DNA ligase prevented incorporation of label into double-stranded fd RFII, which was also produced in the replication system.

Enzymatic replication with DNA species different from fd RFI

The initiating cleavage reaction conducted by gene 2 protein is limited on supercoiled DNA substrates which harbour the replication origin of phage fd¹⁴. The small 2.4-kilobase (kb) plasmid pfdA1, which contains a cloned fragment of the fd origin³, should fulfill these properties. Figure 4d shows that the described in vitro system uses the 261-base pair origin fragment and replicates the plasmid with high efficiency, producing single-stranded DNA.

Previous studies on the mechanism of gene 2 protein revealed a specific reversible binding affinity of the enzyme to its cleavage site in fd RFII_o. This weak interaction is an essential prerequisite for unwinding of fd RFII_o by rep-helicase and DNA binding protein I¹⁷. Consequently, fd RFII_o is a suitable substrate in the replication system for production of circular single strands like fd RFI, if gene 2 protein is present (Table 1). Removal of the 5'-phosphate group in fd RFII_o still produces a substrate (fd RFII_p) which is efficiently propagated by gene 2 protein and the E. coll proteins. However, linear rather than circular single strands are generated in this case due to a missing phosphate group required for ring closure in the first round of replication. Relaxed RFIV, and fd RFII with a nick outside the replication origin, were unsuitable templates in the replication system composed of the four proteins (Table 1).

Biological activity of the replicated single-stranded circles

Faithful DNA replication should produce DNA with the informational content of the template DNA; imprecise circularization of viral single strands should result in a loss of their biological activity. We analysed the *in vitro* replication products in an $E.\ coli$ protoplast system in which double-stranded phage DNA is ~100 times less infective than single-stranded circular DNA (Table 2).

The replication products from a standard incubation assay were deproteinized, because *E. coli* DNA binding protein I interferes with the infectivity of single strands²⁷. Plaque formation in the spheroplast assay (Table 2) showed infective centres

after an enzymatic replication of the DNA, which exceeded infectivity of double-stranded fd RF by two orders of magnitude. Single strands produced by strand unwinding of RF increased this background, but linear viral strands or circular complementary strands were apparently less infective than circular viral strands, as already found for phage Φ X174 DNA²⁸. These results demonstrate effective fd viral strand replication in our system and the precise circularization of the synthesized viral strands by gene 2 protein.

The role of fd gene 2 protein in phage duplex DNA replication

Replication of the viral strand of fd RF is initiated by the phage-encoded gene 2 protein^{29,30}, which introduces a specific single-strand break into the viral strand of the phage RF. The cleavage site of gene 2 protein has been localized in a region of palindromic symmetry¹⁵. This finding and the observation that gene 2 protein cuts both strands of fd RF in the presence of Mn²⁺ (ref. 14) suggest that in physiological conditions two molecules of the enzyme bind to the cleavage region, but only one reacts with the viral strand. Consequently, dimer formation at the cleavage site is believed to be essential in the initial step, and also for processing of rolling circle structures (see below). Concomitant with the cleavage of the viral strand, gene 2 protein may attach transiently to one of the termini of this strand by forming a covalent bond. This intermediate may provide the energy to seal the previously opened strand in a topoisomerase-like manner¹⁴. The attachment of the enzyme to the nicked DNA strand is either followed by the formation of RFIV or the hypothesized protein–DNA complex is

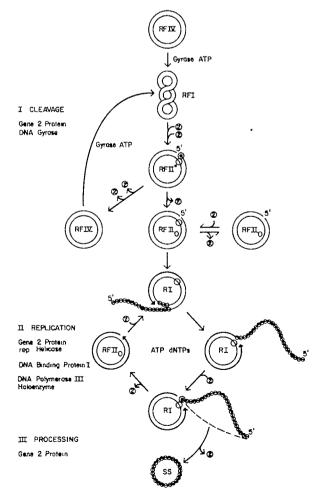

Fig. 5 A model for enzymatic replication of phage fd RF and the involvement of bacteriophage fd gene 2 protein.

fd viral single strands	8,500

Phage fd RF was replicated for 20 min as described in Fig. 1 legend. The incubation was stopped after 5 min at 30 °C by the addition of EDTA. 0.05 M Tris-HCl (pH 8.0) was added to a final volume of 0.3 ml and the sample was treated with phenol. Phenol in the aqueous phase was removed by extraction with ether. The sample was then mixed with 0.2 ml of a protoplast suspension of cells from E. coli K-12 strain W6 (ref. 33). After 15 min at 37 °C the protoplasts were mixed with the indicator strain 1101 and plated on PAM agar.

‡ Transfection rate variable.

rearranged to become active for initiation of the unwinding of fd RFII.

Analysis of the cleavage site in fd RFII has revealed free 3'-hydroxy and 5'-phosphate ends which are substrates for ligation with DNA ligase or for nick-translation with DNA polymerase I^{14,15,31}. However, the complementary strand at the cleavage site seems to be preferentially protected against endonucleolytic digestion with Bal31 nuclease, in contrast to randomly located nicks¹⁷. It has been shown that this protection is due to a reversible binding of gene 2 protein to the cleavage site, which is necessary for specific initiation of the unwinding and the replication reactions. RFIV which is produced in the initiation reaction in addition to fd RFII, needs to be recycled into RFI by DNA gyrase before being processed once more by gene 2 protein (Fig. 5).

The subsequent replication process, outlined in Fig. 5, requires the E. coli proteins DNA polymerase III holoenzyme, rep-helicase and DNA binding protein in addition to the fd gene 2 protein. The rep-helicase accomplishes unwinding of fd RFII in collaboration with DNA binding protein I17. DNA polymerase III holoenzyme extends the 3'-hydroxy end released by the cleavage reaction and proceeds in a rolling circle-type replication. As deduced from experiments carried out in the phage T4 in vitro replication system¹⁹, one molecule of gene 2 protein remains bound to the complementary strand of fd RF during replication. As replication ceases near the origin in the presence of gene 2 protein, this enzyme may serve as a signal for termination after a complete round of replication. A second molecule of gene 2 protein is then required to cut off the replicated single strand, based on the difference in the kinetics of both steps19. The parental RF molecule is released in an open form and therefore immediately used as a template Received 10 December 1981, accepted 1 March 1982

for further replication cycles. For late infection with filamentous phages the occurrence of pulse label in the viral strand of RFIV³² may be due to conversion of RFII molecules into doubly closed DNA by DNA polymerase I and DNA ligase.

The unwound single strands are readily covered by DNA binding protein as replication proceeds¹⁷. This stoichiometric function can be substituted by phage-encoded DNA binding protein (fd gene 5 protein), although catalytic amounts of DNA binding protein I remain essential for unwinding and synthesis of DNA (unpublished results).

In a final reaction, the unwound viral single strand is separated from the parental RF molecule and circularized (Fig. 5). The function of gene 2 protein is solely responsible for this process, as the E. coli proteins in the replication system can be substituted completely by T7 enzymes, that is, T7 DNA polymerase and T7 DNA primase (gene 4 protein)18. However, as we demonstrated by use of the T4 replication system, processing only occurs during concomitant DNA synthesis¹⁹. In the absence of enzymes providing DNA synthesis, long-tailed rolling circle structures are not processed per se, which is consistent with the observation that circular viral single strands are not accepted as a substrate by gene 2 protein¹⁴. We therefore believe that, as for cleavage of fd RFI, a defined DNA conformation in the cleavage region is required for processing the rolling circle intermediate. This situation may be realized by a partially melted double-stranded structure caused by the superhelical tension in fd RFI or due to unwinding, when the replication fork enters the cleavage region of the rolling circle intermediate19

The circularization of phage fd DNA by gene 2 protein basically resembles the sequence-specific topoisomerase reaction of this enzyme on fd RFI. Although we cannot demonstrate the independence on ATP of this reaction, because strand unwinding requires ATP, we have shown previously that the nicking-closing reaction of gene 2 protein on fd RF is unaffected by high-energy compounds like ATP14. As cleavage of singlestranded tails from the rolling circle intermediate occurs regardless of the composition of the 5' end of the tail¹⁹ (Table 1), we conclude that gene 2 protein attaches to the 3'-hydroxy end so as to conserve the cleavage energy for circularization of this DNA. Some affinity of the 5' end at the tail of the rolling circle for the gene 2 protein molecule on the complementary strand may favour the replicated viral strand looping back to the double-strand core, thus facilitating viral strand circularization after a round of replication. Circularization may also be supported by pairing palindromic sequences at the replication origin.

If the 5'-terminal phosphate group of the cleaved viral strand is missing, no circle can be formed (Table 1)17 and gene 2 protein dissociates from the DNA. Thus, gene 2 protein can act in two different ways: either it uses the conserved chemical energy to form a new phosphodiester bond, or, as for the production of RFII_{or} it leads to a decay of the protein-DNA complex, which then simply mimics an endonucleolytic reaction.

We thank Erich Lanka for the donation of DNA primase, Marlies Kaiser, Erna Piaskowski and Ilge Wilhelm for technical assistance and Hermann Bujard, David H. Figurski and Robb Moses for comments on the manuscript.

Transient emission of ultra-high energy pulsed γ rays from Crab pulsar PSR0531

A. I. Gibson, A. B. Harrison, I. W. Kirkman, A. P. Lotts, J. H. Macrae, K. J. Orford, K. E. Turver & M. Walmsley

Physics Department, University of Durham, Durham DH1 3LE, UK

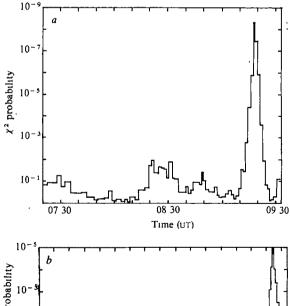

A new experiment has been established to measure the energy spectrum of ultra-high energy (UHE) γ rays (E > 2,000 GeV) from a number of celestial objects. During the commissioning of the equipment several potential sources were studied, including the Crab pulsar PSR0531. UHE γ rays from this object have been observed in previous experiments to be practically all pulsed1-4, but no single observation has been of high statistical significance, and the flux values have been difficult to reproduce⁵. The current observations are based on 34 h of exposure between 25 September and 2 November 1981, and show overall an integral pulsed flux in agreement with our estimate of the average of previous data; most important, they also show strong evidence for a burst of pulsed emission of ~15 min duration. There had been previous suggestions that the Crab pulsar is variable at the energy we used and at slightly lower energies^{1,3}, but at time scales of months or days. The present work is the first to demonstrate short duration (15 min) emission and to offer an explanation of previous apparently discordant results.

The details of the experiment are given elsewhere⁶; it comprises an array of four independent telescopes designed to detect the weak optical Cherenkov emission from electron showers produced in the atmosphere by cosmic γ rays or cosmic-ray particles. It is sited at an altitude of 1,451 m in the Great Salt lake desert, USA, Each telescope contains three paraxial mirrors of 1.5 m diameter focusing the Cherenkov light onto photomultipliers with a field of view of 1.7° FWHM. The array is designed to enable sources to be continuously tracked, with the arrival directions of cosmic γ rays or particles entering the field of view being measured by using the relative time of arrival of the Cherenkov light front at each telescope. When searching for point sources of continuous emission, the detectors are operated with procedures designed to stabilize the threshold energy⁶, which results in an elevated threshold and consequently a lower shower detection rate.

The results reported here are based principally on the universal time (UT) of arrival of cosmic-ray events in the field of view. The search for periodic emission requires the highest possible rate of shower detection, and so the stability procedures were not employed, in order to reduce the threshold energy. The times of arrival of UHE γ rays and the much more numerous background cosmic-ray particles were recorded with a resolution of 1 µs, and with an absolute uncertainty in UT of ~1 ms. After reduction to the Solar System's barycentre, the times were unfolded using an ephemeris derived from contemporary radio observations (A. G. Lyne, personal communication) (period = 0.033263833076 s, derivative = 36.416 ns day⁻¹, epoch = 2444910.5). The phase histograms so produced were searched for evidence of non-uniformity, arising from pulsed γ rays being detected at a uniform rate over the period of observation. Overall, no significant signal was found.

Ideally, periodicity should be searched for by correlating the observed γ -ray arrival time series with the expected light curve, using a likelihood ratio method. This cannot, however, be used in this case because there are no well measured data on the

light curve at these energies. There are only estinates based on measurements at lower energies, to which a triori probabilities cannot be assigned. The usual procedure then adopted is to invoke Poincare's Theorem—that a random tine series of sufficient length, unfolded with an arbitrary period results in a uniform phase distribution. A test for the unifornity of the phase distribution, resulting from the experimental time series being unfolded with a trial period, is taken to inlicate the absence of that period in the time series. Previous searches for periodicity have usually used a binned phase distribution and then either Pearson's χ^2 test for uniformity, or have searched by eye for evidence of an excess in one or more bins, with an allowance for the extra degrees of freedom (d.f.) ariling from the arbitrary choices. These methods suffer from sone disadvantages due to the binning and the arbitrary choices to be made. However, more importantly, none of these constitutes the most powerful test, even if independent tests are combined. The 'uniformly most powerful' test for the uniformity of a circular (phase) distribution, which also avoids the problem of arbitrary choice, is the Rayleigh test⁷ in which the resultant vector, Φ, formed from unit vectors at the phases of the events in the time series is tested for significance. The statistic $2N\Phi^2$ (where N is the number of events in the time series) is distributed as a χ^2 distribution with 2 d.f. This is equivalent to the test for the significance of an amplitude in power spectral analysis, in which the amplitude of any period from a noise series also has a χ^2 distribution with 2 d.f. (ref. 8). This procedure has been extensively checked by testing randomly generated time series, both with and without an added sampled periodic component. The distribution of the resultant, ϕ , was found to conform closely to that predicted in the case of such noise series, and for randomly chosen periods in the experimental series. It has been possible to verify the distribution only down to a probability of 10⁻⁵ due to the limitations of the

10-1 08 00 09 00 1 000 Time (UT)

Fig. 1 The probability of lack of periodicity at the radio period for data in 15 min intervals during observations on a, 23 October 1981, b, 31 October 1981.

pseudo-raniom number generator used, and to the finite length of our experimental data. An added periodic component was always detected at the injected strength but with a sampling uncertainlygiven by the above distribution.

Random sampling of a noise series incorporating a true periodicityshould give, and in our simulations gave, an effect close to the nearest Fourier harmonic of the duration of the observations, deviating from the actual period due to the effects of sampling. To check for periodicities appearing in only part of our data, for errors in the application of the ephemeris or the Solar system barycentre corrections, and for deviations of the Crab pulsar from the ephemeris, periodicity was searched for by sveeping around the pulsar's expected period. The counting ate of the array varies with time due to the changing zenith angle of the source, giving rise to a further spreading of the samping range for a periodicity. Starting at 09.14 UT on 23 October, a strong effect was noticed at the directly adjacent Fourier larmonic to the ephemeris period (the harmonic separation beng based on the total duration of the observation). The charce probability using the Rayleigh test was 10⁻⁴ with 30 d.f., which was felt to be an indicator of pulsed activity; to become consistent with the ephemeris period (that is, at the same Fourier harmonic), the duration of the pulsed emission was required to be shorter than the duration of the observation.

Each night's data were therefore split into 15 min sections, the length being dictated by that required to make the effect seen or 23 October occur in the same Fourier harmonic as the ephemeris period. The sections were each unfolded with the appropriate barycentric period, and the probability of uniformity calculated. Using this procedure the number of d.f had been expanded from 1, in the case of the whole 34 h treated as one set, to 130 d.f. Nevertheless, the chance probability for one of the sections taken on 23 October decreased to $< 10^{-6}$. On 3. October another section showed possible activity with a chance probability of $\sim 10^{-4}$.

To refine the positions of the apparent bursts of periodic emission and also to verify the derived probability values by observing the 'noise' spectrum, a section of fixed length moving in increments of ~ 2 min was used. The result of this procedure is a profile of a data set giving the probability of lack of periodicity (for 1 d.f.) as a function of time with a characteristic duration of 15 min. The profiles of the sets for two nights, 23 and 31 October, are shown in Fig. 1. The total number of d.f. has now expanded to $\sim 1,000$ because of the overlapping of the sections. The peak near the end of the run on 23 October has a Rayleigh test χ^2 value of 37.2 for 2 (internal) d.f., which has a chance probability of 4×10^{-9} . At this peak, $34\pm 5\%$ of the recorded events are periodic, corresponding to an integral flux of $(2\pm 0.3)\times 10^{-10}$ cm⁻² s⁻¹ for the 15 min burst. The threshold energy depends on the zenith angle at which the data are taken and for this observation was 3,000 GeV.

The records of showers arriving during the bursts have been examined for evidence of any properties different from those of 'normal' showers. The total number of showers is higher than that estimated from a period immediately following the burst on 23 October by $18\% \pm 7\%$, but the lack of gain stability procedures make the estimated number of background events imprecise. Our well separated (pitch = 60 m) array of four telescopes enables the showers to be examined in more detail. For example, those showers triggering two or more of the telescopes may be expected to arise preferentially from primary γ rays. This is because of the earlier development of γ -ray initiated showers in the atmosphere, resulting in a slightly wider light pool on the ground. During the burst on 23 October, the showers had been separated into two groups: those occurring during a 20% phase interval at the peak of the light curve, and the rest. The latter group was similar in all ways to the showers in the interval following the burst, while the former group was richer in double telescope responses, with a χ^2 chance probability of 1% which could indicate a wider light pool for some of the events. An alternative explanation could be that the onphase events possess a harder energy spectrum but an analysis

of the photon densities recorded by the individual phototubes shows no significant difference between the two groups. The number of higher multiplicity responses during the 15 min burst was inadequate for this comparison, and the strength of the possible burst on 31 October was insufficient to permit a similar analysis.

The light curve of the Crab pulsar at much lower γ -ray energies has been reported by the Caravane collaboration. In early observations, it showed a main and an interpulse of a few milliseconds duration, and in later observations the interpulse was seen to decrease in amplitude. The light curves inferred from our events occurring during the bursts on 23 and 31 October are shown in Fig. 2 with the relative phase provided by the ephemeris used. All of them show a single pulse of similar shape and long duration of 6 ms FWHM. It is not clear at what absolute phase, with respect to the radio, optical and X-ray pulses, the emission of UHE γ rays is to be expected, nor whether interpulses should occur at this vastly higher

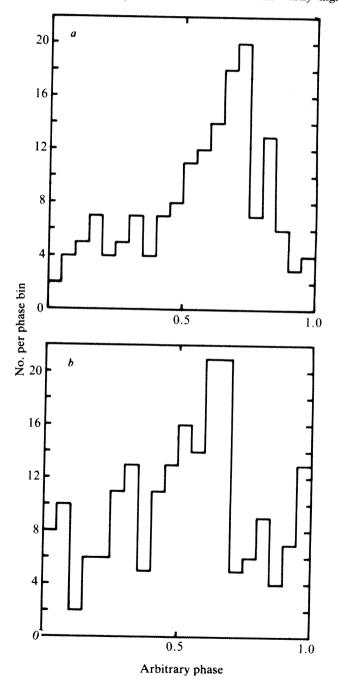

Fig. 2 The light curves for the periods of activity on a, 23 October 1981 and b, 31 October 1981.

photon energy. The derivation of the absolute phase of the light curves in Fig. 2 will require a more detailed ephemeris than that which is now available.

In conclusion, we have shown that the Crab pulsar may be emitting pulsed UHE γ rays in occasional short bursts. A previous balloon experiment¹⁰ at an energy of 1 GeV showed strong variability in pulsed flux between two flights, and during the flight providing the stronger flux, some evidence for variability on a time scale of 1 h. Earlier experiments had reported, at an energy threshold of 2,000 GeV, a time-averaged flux and upper limits near 10⁻¹¹ cm⁻² s⁻¹. The flux of UHE γ rays in the bursts reported above, if averaged over 34 h of observation, suggests a similar time-averaged value and accounts for the previous lack of reproduceability in a straightforward way.

We thank the SERC for funding and for research studentships for I.W.K. and M.W.; Drs T.C. Weekes and H. Tornabene for the loan of equipment; and the commmander and staff of Dugway Proving Ground, Utah for supporting our experimental work.

Discontinuous precipitation reaction in the metal of Richardton chondrite

H. J. Axon & V. J. Grokhovsky

Metallurgy Department, University of Manchester, Grosvenor Street, Manchester M1 7HS. UK

A metallographic and microprobe study was conducted on the H5 chondritic meteorite Richardton, using material that was free of terrestrial corrosion and ablation heating effects. Our observations indicate that initially well annealed and slowly cooled metal experienced an incomplete episode of discontinuous precipitation in the temperature range 350-400 °C, perhaps after mild deformation at some of the metal-silicate interfaces. There were no indications of externally imposed deformation after the 350 °C episode. The mechanism of discontinuous precipitation rather than plane interface growth has implications for the rate of formation of the metallographic structures, and the apparent temperature of this final heat treatment has implications for proposed reheating events identified by isotopic measurements of the silicate minerals that accompany the metal in this meteorite.

The meteorite was observed to fall in 1918 and was originally catalogued1 in terms of its macroscopic features as a veined spherical olivine-bronzite chondrite. In modern terminology this corresponds to the H family of high iron content. The microstructural condition of its silicate minerals has been reported as appropriate to petrological type 5, which Dodd3 has equated with a metamorphic temperature in the range 700-

800 °C, followed by slow (1 °C My⁻¹) cooling to below 500 °C.

Affiatalab and Wasson⁴ measured the Ni and Co content of α , kamacite and γ taenite, in Richardton. Their α : γ relationship crossed the tie-lines derived by Sears and Axon5 for unreheated H chondrites and was thus more appropriate to the reheated material examined by Sears and Axon5. However, Affiatalab and Wasson4 did not consider the possibility of reheating effects in their sample.

Turner et al.6 investigated the argon release from whole-rock samples of Richardton and derived a total argon release age of 4,500 ± 30 Myr. However, they noted that "significant small fluctuations in apparent age occurred over the extent of the release pattern". This observation might suggest some sort of reheating episode.

By contrast, Evensen et al.7 obtained a Rb/Sr age of 4,390 ± 30 Myr from a study of separate chondrules which they removed from the meteorite.

Thus, from isotope studies of the silicates in Richardton there are indications of reheating additional to that encountered in other H chrondrites, but so far there has been no special metallographic study of possible reheating effects as shown by the metal.

Metal in Richardton is usually present with troilite, FeS, and may be encountered either as very small (10 μm) particles embedded within the silicate chondrules, or, as larger (>100 μm) bodies, approaching chondrule size, in the 'matrix' between silicate chondrules.

Bevan and Axon8 have drawn attention to the existence of metallic chrondrules as a feature of the pristine agglomeration structure of chondrites. Metallic chondrules may contain varying proportions of sulphide and silicate phases and thus they complement the spectrum of silicate/metal proportions and structures that have been encountered in the well-recognized silicate chondrules. However, metal is more responsive than silicate to metamorphic forces, thus the matrix metal may be subject to changes of shape by plastic deformation and to changes of shape and size and α : γ structure by diffusive mass transfer. Hence the chondritic nature of matrix metal may become obscured more rapidly than the silicate structures.

The present study was conducted on metal of the larger (= matrix) type. The samples were from unused residual material from the work of Evensen et al.7 (presented by O'Nions). They were mounted as whole-rock samples for metallographic, electron probe analysis and SEM investigation.

Figure 1 shows a typical area of metal as it appears after etching in Nital. The main features of this structure are a new generation of smaller transformation grains of T-kamacite (low Ni, α, b.c.c. Fe-Ni) growing inward from the metal-silicate

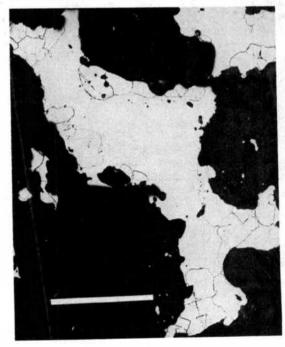

Fig. 1 The structure of a typical matrix metal area in the Richardton (H5) chondrite. Scale bar, 100 µm. At the metalsilicate edge of the large grain of parent kamacite, ~25 smaller grains of transformation structure have developed. There is a small-scale precipitation of γ taenite within the transformation structure; see Fig. 2.

boundary and into the pre-existing monocrystal mass of parent P-kamacite, see Fig. 2. Both P- and T-kamacite are remarkably free from Neumann bands.

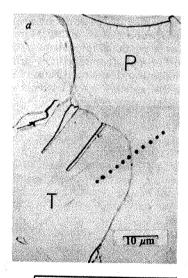

Figure 2 shows that the growth of T has ceased and a parenttransformation interface is detectable. The transformation kamacite is decorated with small elongated particles of taenite (high Ni, y, f.c.c. Fe-Ni) which have developed perpendicular to the parent-transformation (P-T) reaction front. This structure is essentially that of discontinuous precipitation of the type9

P-kamacite → T-kamacite + taenite

The location and distribution of the T grains suggests that they always nucleated at points of local strain on the silicate-metal interface. It appears that cold metal had been subjected to deformation at high-spots in the surrounding silicate, but it is not certain whether the deformation was induced by externally applied forces or was generated by differential contraction between metal and silicate. However, the stress-induced nucleation of the transformation product is confirmed by the occasional appearance of polygonized strain lines within the parent kamacite where it comes into contact with large, unbroken, silicate bodies.

Note that there are additional strain lines that appear to have been formed by the strain effects that accompanied or were generated by the actual progress of the reaction, but this strain is different from that in the nucleating process that we propose above. Some of these considerations have been reviewed elsewhere 10 for the case of manmade alloys.

As usual with chondritic metal¹¹, there is some scatter of bulk nickel content between different individual grains of Pkamacite. However, within each single P+T-kamacite assemblage of Richardton there is a distinct change of nickel content

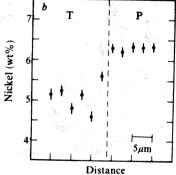

Fig. 2 An enlarged view (a) of the interface between P-(parent) and T-(transformed) kamacite, with the location of microprobe analyses and corresponding (b) Ni contents across the P-T interface. The elongated precipitates perpendicular to the P-T interface are y taenite containing ~50% Ni.

at the transformation interface. The microprobe trace of Ni content across the transformation interface is illustrated in Fig. 2. The small taenite precipitates usually give microprobe analyses in the range 49-50% Ni with a maximum of 52% Ni. The proportions of T-kamacite to precipitated taenite are visually estimated as sufficient to maintain a nickel mass-balance between the parent kamacite and the transformed regions. Reference to the Fe-Ni equilibrium diagram¹² indicates that a taenite of 50% nickel is the equilibrium precipitate at temperatures below ~400 °C.

Thus the composition and microstructure of the matrix metal in Richardton suggests that it developed a shock-free structure at a temperature appropriate to the metamorphic type 5 of its silicates—perhaps 700-800 °C. Slow cooling to the temperature of maximum α solid solubility (~450 °C) allowed the development of P-kamacite with a nickel content at least approaching that maximum.

Below 450 °C cooling may have followed one of two routes, of which we prefer the second. (1) The decreased α solid solubility below 450 °C brought the P-kamacite into a supersaturated condition from which small particles of taenite precipitated in a discontinuous mode as cooling continued. The cellular growth which is visible in Figs 1 and 2 leaves unresolved the mechanism whereby nucleation was induced if the cooling is assumed to have been smooth and continuous. (2) Alternatively, the supersaturated, monocrystal, P-kamacite may have been mildly stressed at locations where relatively large and unbroken bodies of hard silicate made contact with and were able to deform the metal. The temperature of this event cannot be specified but must have been in the low temperature, cold working, range. The deformation was of a slow and gentle nature. The absence of Neumann bands indicated that it was not produced by shock. The evidence lies in the local development of transformation where kamacite is in contact with coarse unbroken silicate bodies but not where it abuts fine matrix material and in the occasional presence of un-recrystallized strain markings around penetrative silicate bodies in the parent

Reheating to 350-400 °C after strain at a lower temperature gives a more unstable condition in the kamacite than is obtained on continuous cooling to that temperature, hence our preference for this production route. In the case of reheating, the taenite precipitates are to be contrasted with the isothermal taenite produced¹³ at higher temperatures in reheated Cañon Diablo kamacite.

The discontinuous precipitation process, now identified for the first time in the cosmic metal of Richardton, involves diffusion within and parallel to the moving transformation front, whereas the previously recognized production of clear or zoned taenite involves diffusion perpendicular to the growth interface. The time required for the production in Richardton of the discontinuous precipitation structure is probably less than would be required for plane interface growth but, nevertheless, appears to be considerable and, if more detailed quantitative information were available an estimate might be attempted. Finally, there have been several studies of meteoritic material artificially reheated at 500 °C and above 13,14 but very little investigation at lower temperatures. To study this possibility we have examined samples of Canon Diablo annealed for 4 weeks at 450 °C and 400 °C. At 400 °C Neumann band alteration was detectable within the mass of the sample but, in addition, at 450 °C there was surface recrystallization, similar to that in Fig. 1 but on a smaller scale, at the cut, and hence deformed edges of the annealed sample.

Distribution and enantiomeric composition of amino acids in the Murchison meteorite

Michael H. Engel* & Bartholomew Nagy

Laboratory of Organic Geochemistry, Department of Geosciences, The University of Arizona, Tucson, Arizona 85721, USA

Early determinations of the amino acid distribution in water extracts of the Murchison meteorite revealed unusual amino acids, including isovaline (Ival), α -aminoisobutyric acid (α -Aiba) and pseudoleucine (Ple), as well as common ones such as glycine (Gly), alanine (Ala) and glutamic acid (Glu)¹⁻¹⁰. Amino acids that could be resolved into their respective D- and L-enantiomers were reported to be racemic (see, for example, refs 1, 3, 5), although small sample size might have hindered the precise determination of D/L values. Using improved chromatographic and mass spectrometric procedures we have now been able to amplify and resolve the partially racemized amino acids, Glu, aspartic acid (Asp), proline (Pro), leucine (Leu) and Ala, in an interior sample of a Murchison meteorite stone. Water-extractable amino acids were more racemized than those recovered by digesting the water-extracted meteorite in 6 M HCl. The amino acid composition of this stone was similar to previous reports¹⁻⁸, including the absence of tyrosine (Tyr), methionine (Met), phenylalanine (Phe) and only minor traces of serine (Ser) and threonine (Thr)9. Serine and Thr are usually considered to be terrestrial contaminations. This is the first report of amino acids in a carbonaceous meteorite which, based on currently accepted criteria, appear to be indigenous but for unknown reasons are not racemic. Confirmation of these findings by other investigators suggests that further examination of amino acids in clean carbonaceous meteorites could be beneficial.

We have analysed a single Murchison meteorite stone (Me 2640, Field Museum of Natural History, Chicago, Illinois: 50.7 g) which has over 90% of its surface covered with an intact fusion crust. Standard precautions were taken to prevent laboratory contaminations 11-13. First, the entire surface (~2 g) of the stone was removed with a high-speed drill. Several interior fragments (39.0 g) were ground to a fine powder using a porcelain mortar and pestle. The meteorite powder and a procedure blank were water-refluxed for 8 h at 100 °C. The water extracts were hydrolysed in 6M HCl for 24 h at 100 °C. The procedure used for cation exchange and derivatization of the water-extractable amino acids has been reported previously¹³. To determine whether hydroxy amino acids, such as Ser and Tyr, were present, the N-PFP, O-PFP-(+)-2-butyl esters were converted to N-PFP, O-acetyl-(+)-2-butyl esters^{14,15} for analysis on effective 61-m long 0.5 mm internal diameter nickel capillary columns coated with Carbowax-20M. Next, the water-extracted residue was dried and then digested in 6M HCl for 24 h at 100 °C. In a control experiment¹³, HCl digestion did not racemize or destroy amino acids in the presence of iron oxides and silicate minerals. The Murchison acid extract was desalted using an anion exchange column followed

by a cation exchange column^{15,16}. The amino acids were then derivatized to N-PFP, O-PFP-(+)-2-butyl esters.

Gas chromatograms of the Murchison water and 6M HCl extracts and of the procedure blank are shown in Fig. 1. Amino acid identifications were confirmed by retention times and coinjection of amino acid standards. The hydrolysed water extract was re-analysed by combined gas chromatography-chemical ionization mass spectrometry (GC-CIMS). Amino acid identifications were confirmed by comparing unknown mass spectra with mass spectra of derivatized amino acid standards (see, for example, Fig. 2). Amino acids recovered by digesting the water-extracted meteorite powder in 6M HCl were, as previously reported¹, less abundant than those removed by water extraction, but the samples were too small to confirm their identities by GC-CIMS. Instead they were identified by co-injection and retention times of amino acid standards whose identifications were confirmed by GC-CIMS.

Amino acid D/L values are listed in Table 1. Some amino acids, such as L-Asp and y-amino-n-butyric acid (GABA), co-eluted; a small, unknown peak co-eluted with D-Pro. For D/L values of carbonaceous meteorites to be significant, the purity of individual amino acid enantiomers must be confirmed by a technique that can subtract co-eluting compounds. Selective ion monitoring (ref. 17 for example) made it possible to remove interfering GC peaks and to obtain and confirm D/L values for Asp, Pro, Glu and Ala in the hydrolysed Murchison water extract. For example, three ions characteristic to Asp (m/e = 420, 280, 262) in CIMS were not present in the overlapping GABA mass spectra. The D/L values for selected ion traces were determined from ion current peak heights. Good correlations were found between D/L values of Ala and Glu determined from integrated GC peak areas and from relative ion intensities. As predicted, the D/L value for Asp was slightly higher (0.30) and that for Pro slightly lower (0.30) when peak interferences were eliminated (Table 1). Figure 3 shows traces of intensities of the three ions common to Ala and not present in overlapping or adjacent amino acid GC peaks of the Murchison water extract.

In these experiments, most of the water-extractable amino acids were partially racemized, whereas the 6M HCl-extractable amino acids were less racemized. These results may not contradict previous reports, because we have analysed a large interior Murchison sample (39.0 g), ensuring recovery of an abundant amino acid fraction for enhanced gas chromatograms as well as for the GC-CIMS ion traces.

The abundances of amino acids detected in the hydrolysed Murchison water and 6M HCl extracts are listed in Table 2. We detected none of the common protein amino acids such as Ser, Thr, Tyr, Phe and Met, that are usually absent in carbonaceous meteorites, in these extracts, although minor traces of Ser and Thr were detected by Cronin and Pizzarello (personal communication) in this stone. Serine is the, or one of the, major components of fingerprints, whereas Thr, Tyr, Met, Phe, Glu, Asp, Pro, Leu and Ala are much less abundant. This suggests that originally the stone did not contain Ser, Thr, Tyr, Phe and Met, and that the other amino acids are not fingerprint contaminations. The four most abundant amino acids in the hydrolysed water extract of the Murchison meteorite were α -Aiba, Gly, Glu and Ala. Cronin et al. have reported similar findings

The absence of Ser, Tyr, Phe and Met in the Murchison meteorite extracts might have been due to their decomposition during sample extraction. To investigate this possibility, we prepared duplicate mixtures consisting of ~0.3 mg of Phe, Tyr, Ser, Met, Glu and Ival. Two hundred milligrammes of the unextracted Murchison meteorite powder were added to one of the mixtures; the other mixture served as a control. Water (1 ml) was added to both mixtures, which were extracted and then analysed for their amino acid contents using the procedure described above for the analysis of the Murchison meteorite water extract. The quantities of Phe (52%), Tyr (13%), Ser (45%) and Met (35%) lost from the mixture containing the meteorite powder during extraction and/or cation exchange

^{*} Present address Geophysical Laboratory, Carnegie Institution of Washington, 2801 Upton St North-west, Washington, DC 20008, USA

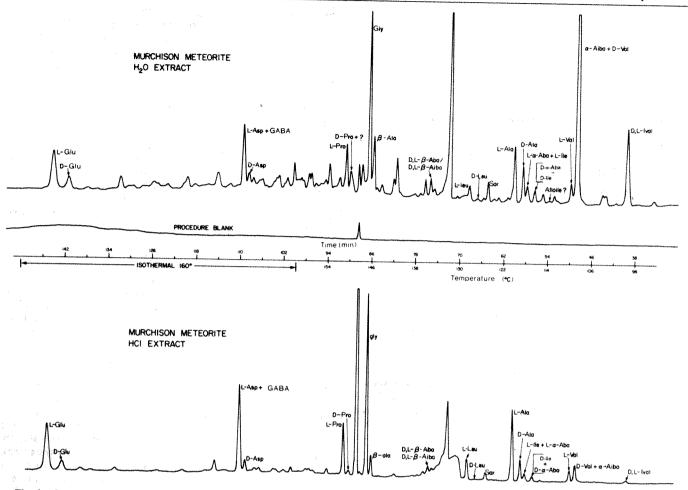

Fig. 1 Gas chromatograms of the procedure blank, water and 6M HCl extracts of the Murchison meteorite. In addition to co-injection of amino acid standards and retention times, all amino acid identifications for the Murchison water extract were confirmed by combined GC-CIMS. The GC and GC-CIMS conditions were identical to those previously reported 13.

were similar to those detected for Glu (40%) and Ival (45%), indicating that if Phe, Tyr, Ser and Met were present in this meteorite stone, they would probably have been detected. Also, there was no deviation from the original D/L values in the control experiments.

The GC and GC-CIMS techniques did not resolve D- and L-Ival. The co-elution of D- and L- α -amino-n-butyric acid (α-Aba) with D- and L-isoleucine (Ile) and their low concentrations made it impractical to use selective ion monitoring to determine their D/L values. Cronin et al. 18 have reported that some amino acid constituents of carbonaceous meteorites, such as Ival and α -Aba, are susceptible to decomposition reactions, which appear to correlate directly with increased residence time of the meteorite on Earth. To resolve the respective D- and L-enantiomers of Ival and α -Aba from the Murchison meteorite, a 3.0 g sample of the Murchison meteorite powder was refluxed twice in water for 2 h at 80 °C. The samples were centrifuged, and the extracts (I and II) were evaporated to dryness and cation exchanged, and then redissolved in water. A slightly modified HPLC procedure 19 was used to isolate and resolve the D- and L-enantiomers of Ival and α -Aba from the two extracts. Isovaline, as previously reported²⁰, was racemic in extracts I (D/L = 0.99 ± 0.06) and II (D/L = 0.99 ± 0.04). α -Aba appeared to be racemic (extract I, D/L = \sim 1.0; extract II, $D/L = 1.13 \pm 0.23$) although its low concentration in the extracts made precise determination of D/L values impossible (Fig. 4).

Some of our results have been independently confirmed in other laboratories. Amino acid abundances in a hot water extract (24 h, 110 °C) of part of the same Murchison meteorite stone (Me 2640) examined by ion-exchange analysis with fluorometric detection (J. R. Cronin and S. Pizzarello, personal communication) were reasonably consistent with those in Table

2. Sample Me 2640 seemed to contain amino acids typical of the Murchison carbonaceous meteorite stones. Fingerprint amino acids, such as Ser, were in low concentrations, and Tyr, Met and Phe were absent. The amino acid abundances and distribution pattern seem virtually to rule out contamination from handling or microorganisms. It is interesting that this stone was enriched in α -substituted amino acids, for example Ival, 2-amino-2,3-dimethylbutyric acid and 2-methylnorvaline, and had fewer amino acids with an α -hydrogen atom than another Murchison stone.

Table 1 Murchison meteorite amino acid D/L values										
Extract	Glu	Asp	Pro	Leu	Ala					
H_2O^*	0.322	0.202	0.342‡	0.166‡	0.682‡					
H ₂ O†	(± 0.044) 0.30	(±0.005) 0.30	(± 0.065) 0.30	(±0.021) ND	(±0.062) 0.60					
HCI*	(±0.02) 0.176 (±0.013)	(±0.04) 0.126 (±0.004)	(±0.02) 0.105 (±0.017)	0.029 (±0.002)	(±0.03) 0.307 (±0.010)					

The experimental errors for the D/L values are shown in parentheses. Approximately 2.0% of the D-amino acids used to obtain the D/L values may be attributed to (-)2-butanol impurities and racemization during 6M HCl hydrolysis. ND, poor resolution did not permit calculation of this value by selected ion traces.

* D/L values were calculated from integrated peak areas and are an average of at least three gas chromatographic determinations.

 † D/L values were calculated from selected ion peak heights and are an average of D/L values determined from three specific ions monitored for each amino acid.

 \ddagger One or more D/L values determined by weighing the peaks (in addition to digital integration).

Table 2 Murchison meteorite amino acid concentrations

Extract	Glu	Asp	GABA	Pro	Gly		nmol g ⁻¹ β-Aiba β-Aba	Leu	Sar	Ala	Ile α-Aba	Val	α-Aiba	Ival
H₂O	18.15	8.48	6.28	13.45	45.79	13.07	5.22	1.91	4.69	15.34	5.98	8.59	107.84	23.57
HCl	6.80	4.02*	3.22*	3.35	14.12	1.25	0.96	0.88	0.57	4.84	0.89	1.09*	1.82*	0.20

 D_L - β -Aba and D_L - β -Aba and D_L -Ile and D_L -a-Aba co-eluted and could not be resolved by GC or selected ion currents because of low abundances and the similarity of mass spectra, respectively. Their respective abundances are reported for the Murchison extracts as average contributions of the two.

A portion of this Murchison meteorite stone and a blank were extracted with hot water and derivatized (N-PFP, O-PFP-(+)-2-butyl esters) by Cronin and Pizzarello (personal communication), and then sent to P. E. Hare for independent GC determinations of the amino acid D/L values. A Perkin-Elmer 900 gas chromatograph with a Perkin-Elmer nitrogen detector, equipped with a 50.0 m×0.3 mm i.d. glass W.C.O.T. chirasilval capillary column, was used. The blank contained only one very small peak with a retention time close to Gly. The D/L values in the derivatized hot water extract of the meteorite were D/L Ala = 0.79, D/L Pro = 0.65 and D/L Glu = 0.56 (P. E. Hare, personal communication).

Only 24 naturally occurring peptides and proteins (3-31 residues long) have been reported not to contain Ser, Tyr, Phe and Met. All are very uncommon in organisms; for example antifreeze glycoprotein 3 (31 residues, isolated from the fish

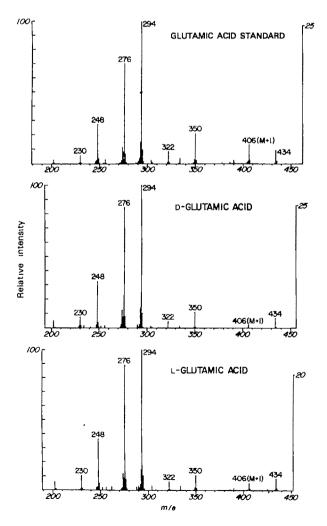

Fig. 2 Mass spectra of glumatic acid standard (top), and of D-glutamic acid (middle) and L-glutamic acid (bottom) in the water extract of the Murchison meteorite. GC-CIMS conditions are given in ref. 13.

Trematomus borchgrevinki), fibrinopeptide B (10 residues, isolated from rhinoceros) and thyroliberin (3 residues, isolated from pig) (M. O. Dayhoff, personal communication). If the Murchison stone we analysed was more than minimally contaminated, it would probably have contained significant quantities of Ser, Tyr, Phe and Met.

The presence of L-Ser in carbonaceous meteorites is generally considered to represent a terrestrial contribution. Assuming that small quantities of L-Glu, L-Ala and L-Pro were introduced into the Murchison stone at the same low level as Ser (0.9 nmol g⁻¹; Cronin and Pizzarello, personal communication), the D/L values can be recalculated after decreasing the L-amino acid abundances proportional to the trace amount of Ser found in this sample. This correction, however, does not significantly alter the D/L values.

Several hypotheses may at least partially account for the occurrence of non-racemic amino acids in this Murichson meteorite stone: (1) terrestrial contamination during entry, impact, collection and/or in the laboratory; (2) various unknown preferential syntheses of non-racemic amino acids during laboratory procedures; and (3) unknown stereoselective chemical synthesis and/or decomposition reactions unrelated to terrestrial sources.

(1) If the stone was more than minimally contaminated before or during impact and/or at any time thereafter, the absence of Tyr, Phe, Met and only a trace of Ser, would not be predicted, as these amino acids are ubiquitous to terrestrial biogenic systems. Also, the $\delta^{15}N$ values of amino acids and other nitrogenous compounds in Murchison are very different from terrestrial δ^{15} N values²¹. If terrestrial contamination by Lamino acids is invoked to account for the Murchison meteorite D/L values, there is either a very unusual contamination source of specific amino acids, or preferential adsorbtion and/or decomposition of specific amino acids, by interactions at probably ambient temperatures of the meteorite organic/inorganic matrices with the intruding material(s). Although preferential adsorbtion of L-amino acids by mineral matrices has been reported (ref. 22 for example), the adsorption or destruction of L-amino acids such as Ala, Glu, Asp, Pro and Leu in preference to others, for example Ser, Tyr, Phe and Met has not. Amino acids extracted from the meteorite with 6M HCl were less racemized than the water-extractable amino acids. To account for these ratios by contamination, the terrestrial contaminants would have to be preferentially and very tightly complexed to the meteorite matrix. In previous experiments in which rocks were soaked in aqueous amino acid solutions for 1,321 h, all the amino acids entering the samples during soaking were extracted from the rocks using the water extraction procedure we used for the Murchison meteorite. Subsequent acid extraction resulted in no additional recovery of amino acids inserted into the rock samples (M. H. Engel and B. Nagy, in preparation). If the Murchison meteorite was contaminated with L-amino acids they should have been removed during the water extraction. L-amino acids introduced into the stone on Earth during the 11 yr before analysis would be predicted to be less tightly bound to, and more readily extracted with, water from the meteorite organic/inorganic matrix than amino acids incorporated in the meteorite some 4.5×10° yr ago. Yet, 6M HCI extraction recovered amino acids showing even less racemization than the water extract, so, in fact, the less racemic

^{*} Concentrations were estimated from the relative abundances determined for the Murchison water extract by selected ion monitoring.

amino acids are more tightly held in this stone than those extractable with water. The finding of non-racemic amino acids. however, makes contamination of the Murchison meteorite a

serious possibility.

(2) Hydrogen cyanide polymers²³ and N-carbamyl amino acids7,8 have been proposed as amino acid precursors in the water extracts of carbonaceous meteorites. Hydrolysis of these precursors to free amino acids would not involve reactions at the asymmetric centres of these compounds, indicating, however, that such precursors, if they were present in this stone, were themselves non-racemic.

(3) Mechanisms have been proposed for the stereoselective decomposition of amino acids²⁴⁻²⁷. If the amino acids in the Murchison meteorite were initially racemic, and if these mechanisms prove applicable, they might indeed account for the D/L values observed. A few mechanisms (for example ref. 28) have been proposed for the extraterrestrial stereoselective synthesis of organic compounds, but it is highly unlikely that amino acids in the Murchison meteorite would be completely racemic had they initially been present in the L or D form²

We therefore conclude that the partially racemic amino acids in this Murchison meteorite stone are probably due to extraterrestrial stereoselective synthesis or decomposition reactions, although the possibility of unusual terrestrial contamination cannot be excluded. Different stones of the Murchison meteorite may be heterogeneous with respect to their carbon

compound compositions.

Optical activity in carbonaceous meteorites infer the possibility of asymmetric chemical syntheses unrelated to terrestrial sources. Although we do not know the specific cause(s) of the optical activity, the independent confirmations of our results strengthen our conclusion that the Murchison meteorite sample we studied was clean and that some of the amino acids are partially racemic.

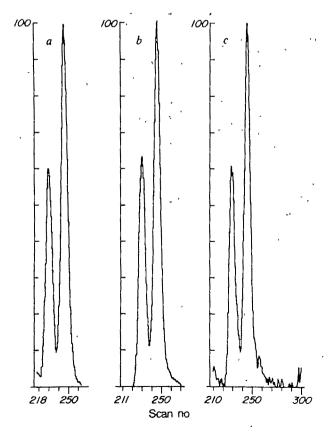

Fig. 3 Selected ion traces for alanine in the water extract of the Murchison meteorite. a, m/e = 218, D/L Ala = 0.60; b, m/e = 216, D/L Ala = 0.63; c, m/e = 320, D/L Ala = 0.58. m/e = 320 is the characteristic M+29 adduct formed by the addition of C₂H₅⁺ to the alanine derivative during chemical ionization.

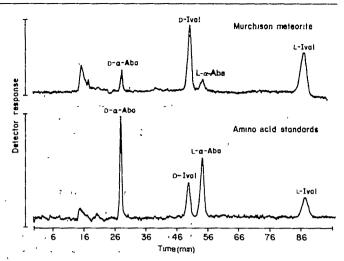

Fig. 4 Chromatograms of the D- and L-enantiomers of isovaline and α -amino-n-butvric acid from extract II of the Murchison meteorite (top) and of isovaline and α -amino-n-butyric acid standards (bottom). D, L-isovaline and α -amino-n-butyric acid were initially isolated from extract II by HPLC using a 25 cm× 2.0 mm i.d. stainless-steel cation exchange column packed with a 5 um cation exchange resin that had been converted to the pyridine form. An aqueous buffer consisting of pyridine (0.2 M) and formic acid (pH 3.2) was used. The buffer flow rate was 0.12 ml min The column temperature was 53 °C. The amino acids were collected using a stream splitter before reaction with O-phthaldialdehyde and subsequent fluorometric detection. The D- and Lenantiomers of isovaline and α -amino-n-butyric acid were resolved using the procedure developed by Engel and Hare¹⁹ for the resolution of basic amino acid enantiomers.

We thank H. Ogino for helping to determine the relative stabilities of amino acids during sample extraction and to prepare additional Murchison meteorite extracts for analysis by HPLC, S. Y. Chang for help with the GC-CIMS analyses, J. R. Cronin, S. Pizzarello and P. E. Hare for their independent examinations of the meteorite sample, K. A. Kvenvolden, L. Margulis and S. L. Miller for comments and E. Olsen for providing the meteorite sample. This research was supported by NASA grant NGR 03-002-171.

Structural features of todorokite intergrowths in manganese nodules

Shirley Turner*, Malcolm D. Siegel† & Peter R. Buseck‡

* Department of Geology, and ‡ Departments of Chemistry and Geology, Arizona State University, Tempe, Arizona 85287, USA † Department of Geological Sciences, Harvard University, Cambridge, Massachusetts 02138, USA

The disordered, cryptocrystalline phases that comprise manganese nodules^{1,2} typically yield broad, diffuse X-ray lines that have led to ambiguity in their identification. Of particular interest is the manganese oxide phase that has been correlated to the presence of copper and nickel in nodules. This host phase has a characteristic X-ray d-spacing of ~10 Å and has been compared with both a naturally occurring material—todorokite^{3,4}—and a synthetic phase—buserite^{5,6}. The structures of those phases have been difficult to decipher, but recent work using high-resolution transmission electron microscopy (HRTEM) has provided insight into the todorokite7 and buserite⁸ structures. Using HRTEM results we now show that the nodule 10 Å phase does have the same structure as nonmarine todorokite9. In addition, structural imaging shows that both nodule and non-marine todorokite exhibit similar disordering phenomena. A unique feature of the nodule todorokite is its intimate and topotactic intergrowth with a possible doublechain oxide. Its paragenetic relationship to todorokite is not yet determined.

By structural imaging of non-marine samples⁷, todorokite was shown to be one of three related intergrowth families that occur in manganese oxides. Each family consists of an intergrowth of variously sized tunnels that differ in sharing either single, double or triple chains of edge-shared [MnO₆] octahedra. Todorokite structures share triple chains, and the large resultant tunnel structures allow for the inclusion of water and large cations. The proposed atomic arrangement of a common todorokite structure is shown in Fig. 1. This tunnel structure

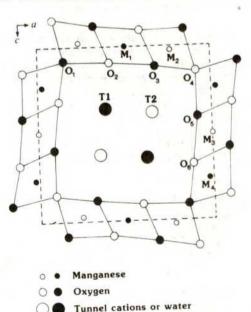

Fig. 1 The proposed atomic arrangement of a common todorokite structure, with three chains of manganese octahedra per side. The structure is projected down the tunnel direction [010]. \bigcirc , b = 0; \bullet , b = 1/2. Dashed line denotes the unit cell.

leads to a fibrous habit, and these fibres are commonly twinned at 120° angles.

Presumed todorokite from manganese nodules has been studied previously by scanning and transmission electron microscopy. Both Siegel¹⁰ and Chukhrov et al.¹¹⁻¹³ found fibrous material in nodules from the Pacific Ocean that contained twinning at the characteristic 120° angle; todorokites with different predominant tunnel sizes were found in these studies. In addition, Chukhrov et al.¹¹ show a high-resolution image of their nodule todorokite viewed perpendicular to the tunnel direction in which different tunnel sizes as well as disordering phenomena are evident.

The nodules we examined were collected from the North Equatorial Pacific near Manganese Nodule Project (MANOP) site S, which is between the Clarion and Clipperton Fracture Zones at about 140° W and 11° N. Details of the morphological and chemical features found in the nodules are presented elsewhere 14. The nodule cores were found to consist largely of moulds of biogenic material such as discoasters, coccoliths and radiolaria. Scanning electron microscope studies of the nodules show that fibres of crystalline manganese oxide occur almost exclusively with the biogenic debris, an association that may have important paragenetic significance. Figure 2 shows

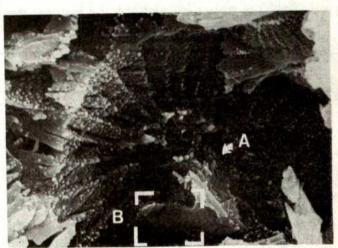

Fig. 2 Close-up of an impression of a coccolith shell. In the centre foreground, fibre tips of todorokite are evident (A). Todorokite fibres overlapping at about 120° angles can be seen in the box B.

examples of overlapping fibres and fibre tips associated with a mould of a coccolith shell. This fibrous morphology is similar to that of non-marine todorokite.

Samples of this core material were crushed and examined in a slightly modified JEOL JEM 100B microscope 15. Due to their fibrous morphology, almost all grains settled onto the microscope grids with their lengths perpendicular to the electron beam direction. A structure image taken in this direction in Fig. 3a reveals triple, quadruple and quintuple chain widths. In other images, double chains, as well as sextuple and septuple chains, are shown. A view down the tunnel direction is necessary to determine the common shared width of these differentlysized tunnels. Unfortunately, the small cross-section of the nodule fibres precludes the use of electron diffraction for this orientation process. In one case, a fibre was fortuitously oriented nearly parallel to the electron beam. Figure 3b shows the image obtained, in which a slightly skewed framework of differently sized tunnels is evident. The estimated tunnel dimensions are labelled in the sketch of Fig. 3c. The image in Fig. 3b confirms that this nodule, 10 Å phase, is formed of an intergrowth of tunnel structures that have a triple chain of manganese octahedra in common. This fibrous 10 Å phase does then indeed have the same structure as non-marine

Disordering phenomena are evident at all levels of

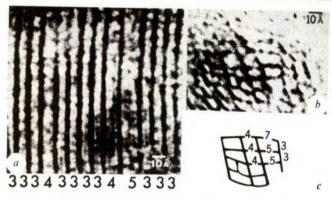

Fig. 3 a, HRTEM micrograph of todorokite from a nodule core, viewed perpendicular to the tunnel direction. The tunnels run from top to bottom in this image. Triple chains of manganese octahedra predominate, but quadruple and quintuple chains are also present. Note the bending of the tunnels on the right side. b, A nodule todorokite fibre oriented with its length parallel to the electron beam direction. c, Sketch of the centre of b with labelled tunnel sizes. The tunnels all have a triple chain of manganese octahedra in common.

magnification of the nodular todorokite material, and they contribute to the streaking of the todorokite diffraction patterns. In some samples, the tunnel structure is disrupted by faults along the chain length. Figure 4a, shows a quadruple chain tunnel becoming a triple chain at a fault. The adjacent triple chains are displaced below the fault. Similar disruptions are evident in the HRTEM image of Chukhrov et al.11 On a larger scale, narrow fibres are gently warped. A distinct bend in a fibre is seen in Fig. 4b. Similar phenomena are found in non-marine todorokite.

In some sample grains, a different phase was seen topotactically intergrown with the todorokite. This other phase gives fringes between 4.5 and 5 Å in width. This spacing may be obscured in X-ray diffraction patterns due to its similarity to a common spacing in todorokite. The identity of this nodule 5 Å phase is uncertain, but structural images obtained from it resemble those we have previously acquired from the doublechain manganese oxides-ramsdellite and groutite. In some cases, todorokite and this 5 Å phase are evident in the same image. In other samples, only the 5 Å phase is seen, and it is associated with apparent relict fibres of todorokite (Fig. 5a). In Fig. 5a, the large, 100 Å-wide fibres resemble todorokite in the way they are twinned at 120° angles. However, high-resolution imaging shows only amorphous regions and fringes from the 5 Å phase (Fig. 5b). It is possible that fibres of todorokite altered to the 5 Å phase. The chemistry of the 5 Å material is

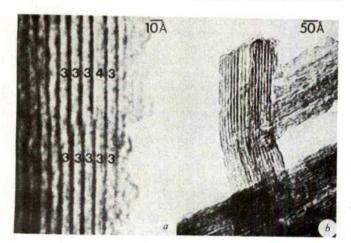

Fig. 4 Disordering phenomena in todorokite. a, A disruption along the tunnel length. A quadruple chain tunnel merges to a triple chain. b, A bent fibre of todorokite.

uncertain at present, but preliminary work has indicated that iron is not present. The chemistry will be important in determining the genetic relationship between the todorokite intergrowths and the 5 Å phase.

This study indicates that further use of HRTEM in the study of the cryptocrystalline manganese nodule phases is warranted both to confirm earlier deductions from X-ray work and to find new phases and their detailed structural features. Such structural information should eventually provide clues to longstanding problems regarding the origin and accretion of nodules. For instance, different environments of formation of nodule todorokite may influence their predominant tunnel size. In the nodule todorokite samples of Chukhrov et al. 11-13, a predominant [100] width is 14.6 Å which corresponds to quintuple chains of manganese octahedra, whereas in our samples the predominant width is of triple chains. Perhaps a layer 10 Å phase (analogous to buserite) occurs in other environments. Two other manganese oxide phases—birnessite and vernadite have been proposed to occur in nodules. Both these structures are poorly understood and HRTEM should provide insight into their nature. A final problem is the location of transition elements such as Cu, Ni and Co in nodule phases. Use of structural imaging with concurrent microanalysis should firmly establish the identity of the host phases.

Pulsating flow of a plastic fluid

N. Phan-Thien & J. Dudek

Department of Mechanical Engineering, The University of Sydney, New South Wales 2006, Australia

It has been observed^{1,2} that when a polymeric solution flows through a circular pipe under a pressure gradient which varies periodically about a non-zero mean, the mean volumetric flow rate increases over that which is due to the mean pressure gradient alone. The magnitude of this flow enhancement depends on the fluid properties and is a function of the mean pressure gradient and the amplitude and the frequency of its varying component. Theoretical work¹⁻⁶ has indicated that this phenomenon is due to the shear-thinning property of the polymeric fluid. More generally, the flow enhancement arises because of the non-linear relationship between the stress and the strain rate which causes the effective viscosity to decrease. Indeed, we show here that a flow enhancement is possible for a Bingham fluid⁷.

This fluid does not deform below a certain yield shear stress $\tau_{\rm v}$; above this yield shear stress it flows like a newtonian fluid (with constant viscosity) and is thus not shear-thinning in the normal sense. However, a power analysis shows that the extra power required to pulsate the flow is greater than that required to generate the extra flow enhancement under a steady pressure drop. Consequently there is no economic reason to pulsate the flow. The set-up of the experimental rig is shown in Fig. 1. A peristaltic pump B was used to circulate the test fluid from a reservoir A which was immersed in a thermal bath. The temperature was regulated to ±1 °C. Pressure gradient noises in the pump were effectively damped out using two smoothing bottles C in series. The pulsatile pressure gradient was generated by a piston E driven by an offset circular cam D. High frequency components of this pulsatile pressure gradient were damped out using another smoothing bottle F. In this arrangement the fluid flowed under a pressure gradient of the form

$$\partial P/\partial z = -P_0(1 + \varepsilon n(t))$$
 (1)

where P_0 is the mean pressure drop per unit length, n(t) is a near perfect sinusoidal function of time and ε is the relative amplitude of the pulsatile pressure gradient. To measure P_0 , a

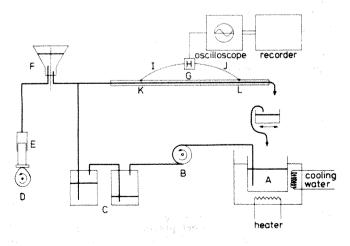

Fig. 1 Schematic arrangement of the pulsating flow experiment.

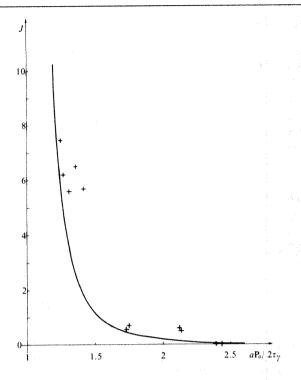

Fig. 2 The base flow enhancement. Solid line is the theoretical curve based on equation (5). +, Data on a 10% bentonite solution taken at a frequency of 0.1 Hz, temperature (24.5 ± 0.5) °C and the amplitudes (ϵ) vary between 0.3 and 0.4.

differential pressure transducer H connected to the test section G at K and L was used. To avoid the attentuation in the amplitude of the pulsatile pressure gradient, we measured ε by mounting the transducer H directly on K and disconnecting the plastic tube J. The efflux was measured by the conventional beaker and stopwatch method.

The test fluid is an aqueous suspension of bentonite at 10% by weight. The bentonite powder (manufactured by Magcobar) conformed to API specification 13A. On a wet screen analysis it leaves a maximum of 4% residue on a US standard sieve no. 200 (nominal opening of $74 \mu m$). At low shear rate the bentonite suspension behaves essentially like a Bingham fluid. That is, in a simple shear flow of shear rate $\dot{\gamma}$, the shear stress is given by (note that τ is an odd function of $\dot{\gamma}$)

$$\tau = \eta \dot{\gamma} + \tau_{v} \operatorname{sign} (\dot{\gamma}) \tag{2}$$

where sign $(\dot{\gamma}) = 1$ if $\dot{\gamma} > 0$ and sign $(\dot{\gamma}) = -1$ if $\dot{\gamma} < 0$. Using a commercial vane viscometer (Wykeham Farrance Engineering Ltd) and an Instron Model 3250 Rotary Rheometer with a cone (2°) and plate (2 cm radius), we found that $\tau_y = (6.4 \pm 0.5)$ Pa.

To quantify the effect of the pulsatile pressure gradient, we define a flow enhancement I as

$$I = (\langle Q \rangle - Q_0)/Q_0 \tag{3}$$

where $\langle Q \rangle$ is the average flow rate (the angular brackets denote a time average) and Q_0 is the flow rate due to the mean pressure gradient alone.

At low value of ε (ε < 0.4) and keeping the mean pressure drop and the frequency of the pulsatile pressure gradient fixed, we found that I is proportional to ε^2 , which was already noted by Barnes et al.^{1.2} for polymeric liquids. However, for the bentonite solution tested we found I to be independent of the frequency ω of the pulsatile pressure gradient, up to a value of $\omega \sim 1$ Hz. The experimental findings at $\omega = 0.1$ Hz are dis-

played in Fig. 2 where we plotted the base flow enhancement $J = I/2\varepsilon^2 \langle n^2 \rangle$ against a dimensionless pressure drop $aP_0/2\tau_{\gamma\gamma}$ where a = 3.2 mm is the inner radius of the test section. (Note that $2\langle n^2 \rangle = 1$ for a sinusoidal n(t).)

To compare the experimental findings with the theory based on the Bingham fluid model we use equations (1) and (2) in the equations of motion neglecting body forces and the fluid inertia. The latter assumption is reasonable in view of our Reynolds number (based on ω and a) is always <0.01. It can be easily shown that the flow enhancement is given by

$$I = 2\varepsilon^2 \langle n^2 \rangle J + o(\varepsilon^2) \tag{4}$$

where

$$J = (\phi^4 - \frac{4}{3}\phi^3 + \frac{1}{3}), \qquad \phi = aP_0/2\tau_v \tag{5}$$

Equations (4) and (5) show that the theoretical flow enhancement is independent of the frequency and that it is proportional to ε^2 for small ε^2 . Furthermore a knowledge of the yield shear stress (and not the viscosity η) and the mean pressure drop per unit length is sufficient to determine the base flow enhancement J. The theoretical base flow enhancement is plotted in Fig. 2. Clearly, in view of a large experimental error which must exist when taking the difference between two quantities of the same order of magnitude, $\langle Q \rangle$ and Q_0 , the agreement between theory and experiment is very satisfactory.

To find out whether pulsating a pipe flow of a Bingham fluid is also economically viable we must also look at the net power requirement. Now the net power required to pulsate the flow is

$$\begin{split} W &= -\left\langle Q \frac{\partial P}{\partial z} \right\rangle \\ &= \frac{\pi a^4 P_0^2}{8 \, \eta} \left(-\frac{4}{3} \phi^{-1} + \frac{1}{3} \phi^{-4} + \varepsilon^2 (1 + \phi^{-4}) \langle n^2 \rangle + \mathrm{o}(\varepsilon^2) \right) \end{split}$$

In steady conditions we need a pressure drop per unit length of

$$P' = P_0(1 + 2\varepsilon^2 \langle n^2 \rangle (\phi^{-4} - 1) + o(\varepsilon^2))$$

to generate a flow rate $\langle Q \rangle$. Thus the power required in steadystate conditions which yields an identical (to $o(\varepsilon^2)$) flow rate is W' = P'(Q). The extra power required to pulsate the flow is

$$\Delta W = W - W'$$

$$= \varepsilon^2 \langle n^2 \rangle (\phi^8 - 4\phi^4 + \frac{8}{3}\phi^3 + \frac{1}{3})(\phi^4 - 1)^{-1}$$

$$\times (\phi^4 - \frac{4}{3}\phi^3 + \frac{1}{3})^{-1} + o(\varepsilon^2)$$

If terms of $o(\varepsilon^4)$ and higher are neglected, ΔW is seen to be always positive. Consequently there is no economic advantage in pulsating the flow of a Bingham fluid. This conclusion does not agree with that of Barnes et al.2 who modelled their polymeric fluids by an Oldroyd model.

This research is supported by an ARGC grant (F 79 1559 7R). We thank the Oil Drilling and Exploration Company for donating the bentonite sample.

Steam explosions of molten iron oxide drops: easier initiation at small pressurizations

Lloyd S. Nelson & Patricia M. Duda

Sandia National Laboratories, Albuquerque, New Mexico 87185, USA

If a light water nuclear reactor core were to overheat, hot molten materials might contact liquid water and cause a steam explosion damaging to the containment structure¹. To predict such an occurrence and the ensuing damage, we in the Sandia National Laboratories have been performing large² and small^{3,4} scale experiments coupled with analytical modelling^{5,6}. As part of this effort, we have been releasing single drops of a core melt simulant, molten iron oxide, into liquid water. Small steam explosions are triggered shortly afterwards by applying a pressure pulse to the water. The threshold peak pulse level above which an explosion always occurs was studied at ambient pressures between 0.083 and 1.12 MPa. Unexpectedly, the threshold decreased to a minimum in the range 0.2-0.8 MPa and then increased again. The observation that gentle pre-pressurization meant easier triggering should improve the predictive capability of our models and suggest conditions for reducing the hazards of these explosions.

A steam explosion can occur when a hot, molten material contacts liquid water. The explosion, which sometimes generates destructive shock waves, is caused by the fragmentation of the melt and rapid transfer of heat to the water with very rapid generation of steam. Explosions such as these pose serious hazards whenever large quantities of molten materials are handled, for example, in the metallurgical and papermaking industries. (Cronenberg and Benz¹ recently reviewed steam explosions with particular emphasis on nuclear reactor safety.)

Melts that would result from a nuclear reactor core meltdown, called coriums⁷, would be composed of various mixtures of UO2 fuel, zircaloy cladding, and stainless steel structures, oxidized to some extent by contact with steam at temperatures near 2,000 K. We have been studying iron oxide because it can be a major component of some of the coriums⁸; it also simulates some of their physical and chemical properties. Single drops are used because it enables excellent control of the many parameters involved in the interactions.

Individual 2.9-mm diameter pendant drops of iron oxide were heated to 2,230 K with 100-200 W of focused continuous wave CO₂ laser radiation^{4,9}. The drops, supported on the bottom end of a vertical iridium wire, were positioned a few millimetres above the surface of liquid water held in a polymethylmethacrylate tank 152 mm square and 300 mm deep. The tank contained a water heater, stirrer and thermometer. At various distances from the bottom of the tank, a pressure pulse was generated in the water by the capacitor discharge explosion of a submerged wire. The magnitude of the pulse which triggered the steam explosion was varied by raising or lowering the exploding wire. The interactions were analysed using high speed cameras, a lithium niobate pressure transducer 10,11 hung in the water, and by examination of the iron oxide residues after the interactions.

The entire apparatus was enclosed in a steel pressure chamber which had a zinc selenide window12, a transparent fused silica window, and a thick glass window for passage of the laser radiation, pyrometer viewing and photography, respectively. The oxygen partial pressure within the chamber was held at ≈0.02 MPa to maintain the composition of the drop at FeO_{~1.2} (ref. 13). The total chamber pressure was varied from local atmospheric (0.083 MPa) to 1.12 MPa by pressurizing with Ar or N₂. After shaking the molten drop from the wire, the interaction was initiated by exploding the wire \approx 125 ms after the drop entered the water.

The steam explosion produces a steam bubble which alternately grows and collapses for several complete cycles. Each bubble collapse produces a pressure pulse in the water. These pulses, along with the triggering pulse, cause progressively finer fragmentation of the melt, presumably due to collapse of the film boiling layer that surrounds each melt particle at the beginning of each cycle. Bubble growth is caused by the rapid transfer of melt enthalpy to the water with each breakup of the melt. The final debris consists of finely divided iron oxide with average particle diameters in the tens of micrometres range. Further description of the experiments is given in refs 4 and 14.

Recently, we have studied the effects of varying the basic parameters involved in the interactions¹⁴, including ambient pressure. The effects of increased ambient pressure on vapour explosions have been considered previously, both analytically^{6,15–18} and experimentally (several experimental reports are cited in ref. 6). It seems established that for given triggering conditions, it should become progressively more difficult and eventually impossible to initiate an explosion as ambient pressure is increased. However, it has been neither predicted nor observed that initially it becomes easier before it becomes harder to trigger an explosion as this pressure increases, at least for single drops of a melt such as ours.

The easier triggering was first observed as a sharp drop in the threshold triggering peak pressure, Δp , required to initiate an explosion as ambient pressure, P_{∞} , was increased. This is shown in Fig. 1, which indicates the occurrence or absence of an explosion as these two parameters were varied; water temperature was held constant at 297 K. Note the abrupt dip in threshold trigger pressure from $\Delta p \approx 0.4$ to <0.2 MPa as P_{∞} is increased from 0.083 to 0.2 MPa, and the broad minimum in Δp which extends to $P_{\infty} \approx 0.8$ MPa.

As chamber pressure is increased at constant water temperature, the water subcooling also increases. (The subcooling of a liquid is the difference between its boiling temperature at a given ambient pressure and its actual temperature. Subcooling is normally considered to be one of the parameters which governs heat transfer in film boiling situations of the sort that prevail in our experiments.) Because at a given ambient pressure

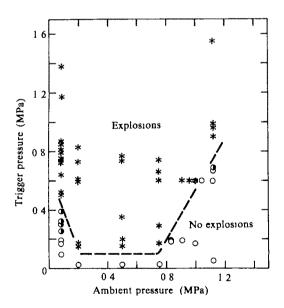

Fig. 1 Plot of peak triggering pulse pressure against ambient chamber pressure for the interaction of a single 2.9 mm drop of molten iron oxide at 2,230 K released into water. Temperature of the water was 298 K for the points at an ambient pressure of 0.083 MPa; for all other experiments, it was 296 ± 1 K. *, Vigorous explosion with fine fragmentation. ①, Sluggish interaction, often with an explosion ≈ 0.1 s after the triggering pulse. O, No explosion.

(

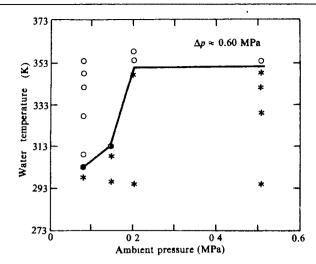

Fig. 2 Effect of water temperature on the interaction between single drops of molten iron oxide and liquid water as ambient pressure, P_{∞} , varies. A constant peak trigger pressure, Δp , of ~ 0.60 MPa is used in all experiments. *, Vigorous explosion with fine fragmentation. \bigcirc , No explosion. *, Duplicate experiments: one drop exploded, the other did not.

steam explosions normally become easier to initiate as water subcooling increases⁶, the question arises as to whether the increased ease of initiation as ambient pressure increases is due primarily to water subcooling.

We therefore performed a series of experiments whereby ambient pressures were increased but water temperatures were also increased appropriately to maintain constant water subcooling. We again found that at an ambient pressure of 0.2 MPa the trigger level required dipped to <0.3 MPa; however, it increased more rapidly than in Fig. 1 to \approx 0.7 MPa at $P_{\infty} = 0.5$ MPa. The increased ease of triggering a steam explosion at increased ambient pressures, therefore, seems to be due only partially to water subcooling effects.

We then investigated the easier triggering as pressure increased by varying water temperature and ambient pressure in a different way, keeping the triggering level fixed at $\Delta p \approx 0.6$ MPa. Because it becomes more difficult to initiate steam explosions as the water becomes hotter at constant ambient pressure⁶, the threshold temperature above which explosions no longer can be initiated for a fixed triggering level becomes another measure of the ease of initiating a given melt-water interaction.

The measured threshold temperatures shown in Fig. 2 were 300 and 310 K for $P_{\infty} \approx 0.083$ and 0.14 MPa, but rose sharply to 350 K for $P_{\infty} \approx 0.20$ and 0.50 MPa. This sharp rise again indicates that triggering the steam explosion of a single drop of molten iron oxide becomes easier at ambient pressures a few times greater than atmospheric.

Although the effect is as yet unexplained we feel that the easier initiation as ambient pressure increases may have an important role in the triggering and propagation of a large scale steam explosion through a coarsely premixed dispersion of melt in water. For example, if a quasistatic localized pressurization should occur in the early stages of the explosion (water temperature would probably remain essentially constant), this would increase the sensitivity of the pressurized portion of the array to subsequent pressure disturbances generated in the system. This may aid the transmittance of the explosive interaction throughout the system.

Optical spectroscopy in a shocked liquid

G. E. Duvall*, K. M. Ogilvie*, R. Wilson*, P. M. Bellamy* & P. S. P. Wei†

*Department of Physics, Washington State University, Pullman, Washington 99164-2814, USA

Scientists in the USSR have reported chemical effects of shock waves in condensed materials which they cannot attribute to the effects of pressure and temperature. They postulate the existence of "catastrophic" chemical effects in the region of near-discontinuous change called the "shock front"1.2. Direct testing of this postulate requires time-resolved observations of chemical processes as the sample is traversed by the shock, and to this end we report here the development of methods for the measurement of temporal changes in the electronic spectra of condensed materials in such conditions. The time resolution is about 3×10^{-8} s.

Measurements in liquid CS₂ show unexpected increases in reflectivity and absorption as well as large shifts of absorption band edges towards the red at shock pressures of <12 kbar. The significance of these observations is not yet understood, but it is clear that electronic, and therefore chemical, changes are taking place in transient conditions not normally accessible to chemical experimentation.

In 1920, Parsons reported unsuccessful attempts to produce artificial diamonds by compression of carbonaceous materials with shock waves³. Forty-one years later the feasibility of the conversion was established4. Work before 1961 had shown that profound changes could be produced in metals by strong shock waves; later experiments, carried out principally in the USSR, have demonstrated the feasibility of driving a variety of chemical reactions by compression with moderate to strong shock waves^{1,2}. While these experiments, called 'recovery experiments' because analysis takes place only on samples collected after being shocked, were in progress, various types of dynamic shock experiments were developed and used for studying mechanical, thermal, electrical and optical properties of condensed matter⁵. These latter experiments are most successful if plane one-dimensional shock waves are used to compress the samples. Such shock waves can be produced in the laboratory by planar impact of a projectile on the sample.

The oldest known chemical reaction initiated by shock waves is detonation in high explosives. Several years ago, moved by the difficulty of making dynamic measurements in detonation, Sheffield undertook dynamic measurements on a non-explosive material, liquid CS₂, to establish its decomposition, to provide evidence that dynamic measurements in such a system are possible and to measure kinetic parameters of the process^{6,7}. The success of his measurements led to a desire for measurements more directly related to chemical processes and thus to the development of spectroscopic techniques reported here.

Optical spectroscopy in shock experiments has been attempted before but with qualified success⁸⁻¹¹. In our experiments, a liquid sample is contained in a penny-shaped cell, bounded front and back by transparent sapphire disks and on the sides by a cylindrical brass shell. The shock is created by impact of a flat-faced projectile on the plane face of one of the sapphire disks. Just before impact a xenon flash lamp is pulsed, producing a spectrally broad light which traverses the sample assembly, passes through a grating spectrograph and is recorded on 35 mm film by means of a rotating mirror streak camera. The record on the film has wavelength varying across the film strip, time varying along the strip and density varying with reflectivity or transmissivity of the sample. For reflection experiments the light source is external to the target and projectile assemblies. Light is brought into the cell through the sapphire disk opposite the impact side and in a direction very close to normal. It comes out near the normal and is reflected through the entrance slit of the spectrograph. For transmission experiments the flash lamp is mounted in the projectile. Contacts on the face of the projectile connect with high voltage leads in the target just before impact. The power source is triggered soon afterwards and light transmitted through the cell is reflected

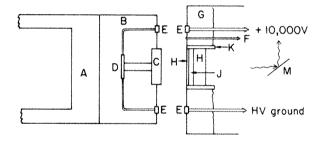

Fig. 1 Schematic representation of light transmission experiment. A, aluminium body of projectile; B, PMMA/epoxy projectile head; C, sapphire impactor; D, Xe flash lamp; E, high-voltage connectors; F, trigger pin for oscilloscopes; G, epoxy target body; H, sapphire plates of test cell; J, cavity containing liquid CS₂; K, brass container for test cell; M, mirror which reflects light into objective mirror of spectrograph.

into the spectrograph as before. The subject material has been CS₂ at room temperature and an initial pressure of 1 atmosphere. Thicknesses of the CS_2 layer vary from $\sim 150 \,\mu m$ to < 1 µm, and final pressure in the sample is reached by reverberation between the sapphire plates. Reflection records obtained thus far are in the UV, approximately centred on the transmission region at 2,700 Å between two absorption bands¹². The records show transmission as expected before the shock reaches the sample and momentary extinction as the shock enters the sample, followed by reflection all across the film as pressure in the sample rings up to its final value. Reflection coefficients are estimated to be >0.2 at 80 kbar and >0.6 at 120 kbar. At a final pressure of 80 kbar, reflection remains constant after the first three or four reverberations. At 120 kbar, it reaches a peak and then decays with a time constant of about 280 ns. Transmission experiments show a shift of absorption edges towards the red at an initial shock pressure of ~ 5 kbar by amounts which cannot be explained simply as thermally enhanced excitation of normal vibrational states. At a pressure of < 20 kbar, extinction through the range 2,500-4,000 Å is complete. Transmission in the visible is almost completely extinguished at 120 kbar in this reverberation geometry.

¥,

A schematic diagram of the transmission experiment is shown in Fig. 1. The projectile is 10.16 cm in diameter and 20.32 cm long, driven by high-pressure gas13. The reflection experiment differs from Fig. 1 in that the flash lamp is replaced by a cavity behind the impactor and the left face of the sapphire impactor is coated with a light absorber to minimize two-way transmission through the cell. When two-way transmission is desired the left face can be made a mirror. With the reflector in this position, it is unshocked during the significant part of the experiment.

A transmission record is shown in Fig. 2. The region 3,580-2,900 Å is an absorption band; there is another below 2,680 Å, but its edge is obscured by decreasing sensitivity of film and grating. At impact the reflection from air-sapphire interfaces between target and impactor is reduced, causing the barely perceptible increase in density across the film at a. At b, the shock initiated at impact has traversed the 2 mm face of the cell and entered the CS2. At c, the shock in CS2 has traversed the cell for the first time and reflected from the inside face of the back sapphire plate. The strength of the first shock is ~5 kbar. On reflection this increases to 12 kbar, which is apparently enough to cause complete extinction of the transmitted light in the lower transmitting region. Temperatures for these first two shocks were calculated to be 398K and 482K respectively; the apparent change in the absorption edge which is initially below 2,670 Å is > 0.23 eV; for the upper edge at 3,580 Å the change is 0.11 eV for the first shock. The shift due to the second shock in the upper edge is ~ 0.12 eV. Transmission in the visible (not shown) was little affected at the final pressure of ~ 55 kbar.

The record from a reflection experiment is shown in Fig. 3. In this experiment the left-hand face of the sapphire impactor, C in Fig. 1, is silvered, there is no flash lamp, and the record to the left of b in Fig. 3 represents two-way transmission through the CS₂ sample. The first shock, with amplitude of 8 kbar, enters the CS₂ at point b and completes its traverse of the CS₂ at c. The extinction of light during this interval is similar to that recorded in Fig. 2, but pressure of the first shock is larger. ~8 kbar, and calculated temperature is 427K. Reflection of the shock at the second CS2 sapphire interface at c initiates

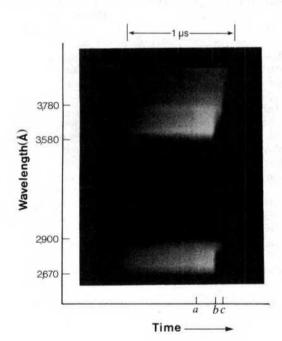

Fig. 2 Time-resolved spectrogram of light transmission through the CS2 filled cell shown in Fig. 1. Light regions represent transmission. a, impact occurs; b, shock arrival at sapphire-CS2 interface; c, second shock traversal of CS2 cell (first reverberation). CS_2 sample is 145 μm thick and ~ 3 cm in diameter. Time resolution is ~30 ns; spectral resolution is ~30 Å. Final pressure is 55 kbar. Shot number 81-010. ×3.2.

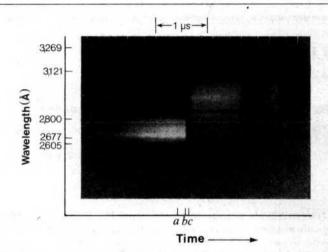

Fig. 3 Time-resolved spectrogram of two-way transmission through and relection from a CS2-filled cell. a, Impact occurs; b, shock reaches front interface of CS2-sapphire; c, shock completes first traverse of CS2 cell. Cell thickness is 69 µm. Time and spectral resolutions as in Fig. 2. Final pressure is 80 kbar. Shot number 80-010, ×1.6.

the optical reflection process. The strength of the reflection in the next few reverberations builds up to a value which remains constant until the shock reaches the rear face of the second sapphire. This is corroborated by a photomultiplier record (not shown) of the total light intensity plotted against time, integrated over the wavelengths indicated in Fig. 3. Final temperature at 80 kbar is ~870K.

Measurements of resistivity of the CS2 in these shock conditions give values of the order of $10^{+4} \Omega m$, which is too large to explain either the observed extinction or reflection. Transmission spectra in the visible show that transmission for wavelengths ≥4,000 Å persists at a final (ring-up) pressure of 55 kbar. This confirms qualitative experiments reported elsewhere 14.

Final pressure in these experiments is reached by a series of reverberations, so they are not directly comparable to single shock experiments to the same pressure. Final temperature is less in the reverberation cell than in a single shock.

These experiments should allow processes of molecular interaction which have heretofore been inferred from indirect evidence to be observed directly and open new avenues for studying the dynamics of chemical processes in highly compressed matter. Further details can be found in ref. 15.

We acknowledge the continuing support of this research by the United States Office of Naval Research under contract no. N00014-77-C-0232 and the encouragement provided by Dr Richard S. Miller.

Lipids in Harmattan aerosols of Nigeria

R. E. Cox*, M. A. Mazurek† & B. R. T. Simoneit‡

- ‡ Institute of Geophysics and Planetary Physics, University of California, Los Angeles, California 90024, USA

Terrestrial lipid detritus has been found in some pelagic sediments at great distances from land (for example, in the North Atlantic) and aeolian transport has been invoked as one input mechanism to explain this observation¹. This is supported by the presence of the same lipids in oceanic aerosols, presumably derived from major wind systems originating on land^{2,3}. Thus, it is vital to examine whether this lipid signature is observed on the continent in the ambient aerosols towards their source regions (such as the Harmattan). We have analysed solvent-extractable lipids in Harmattan aerosols collected in Nigeria and report here that the distributions of hydrocarbons indicate both a major contribution of plant waxes and lesser components of a complex composition, believed to originate from algal and other microbiological detritus in desiccated lacustrine muds or from eroded, recycled sedimentary organic matter.

The origins, nature and fate of Saharan dusts have been discussed elsewhere⁴. Organic material in dust samples collected off the coast of north-west and south-west Africa has been analysed^{2,3} but most of the samples are believed to have a different source from the Harmattan dusts. The Harmattan aerosols are believed to arise in the Faya Largeau area of the Chad Basin⁵ and are carried by the prevailing winds over Nigeria and other parts of West Africa to the Atlantic Ocean (Fig. 1). Analysis of organic matter in dusts collected off the west African coast has indicated a high concentration of organic detritus³. For a better understanding of the nature and origin of the organic matter, it was desirable to sample the dust aerosols closer to their presumed origin. High-volume air samplers with quartz fibre filters capable of collecting particulates down to ~1 µm diameter were used6. Samples were collected in varying conditions of visibility at several locations in Nigeria (Fig. 1) over two Harmattan seasons. A major problem in organic analysis of aerosols is distinguishing between natural and anthropogenic materials. Anthropogenic components could be present in the local atmosphere and would originate from emissions by vehicle exhausts, kerosene lamps and stoves.

The locations, sampling dates and analytical data for the samples that we analysed are presented in Table 1. Total solvent-extractable organic matter (lipids)⁶ was 600–6,000 ng m⁻³ of air, of which 100–2,000 ng m⁻³ consisted of hydrocarbons and the total loadings of aerosol were typically 300–900 µg m⁻³ (Table 1). Data are shown for samples collected on typically dusty days at a site in Jos (samples 1–4). This site was chosen to minimize both the effects of local soil dust (elevation 10 m above ground) and anthropogenic interferences (outside the town and upwind of the prevailing northeasterly winds). Further samples were taken in Jos (number 6) and downwind from Jos (number 12). The samples from Sokoto and Kano were taken upwind from the cities and at Maiduguri in the south-west sector (wind from north-east). The samples from Ibadan were taken within the city.

Examples of typical gas chromatographic-mass spectrometric (GC-MS) total ion current traces, equivalent to gas chromatograms, for total hydrocarbon fractions are shown in Fig. 2. An

Present addresses: * School of Natural Resources, University of the South Pacific, PO Box 1168, Suva, Fiji; † School of Oceanography, Oregon State University, Corvallis, Oregon 97331, 118A

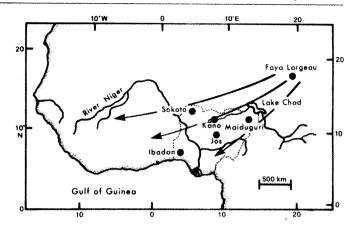

Fig. 1 Location map of the sampling sites and Harmattan wind in West Africa.

outstanding feature of sample 1, upwind from Jos is the value of the carbon preference index (CPI)^{6,7} of 7.8 for the higher n-alkanes exhibiting the typical plant wax predominance of odd carbon number alkanes and maximum at n-C29 (ref. 8). For comparison, the typical CPI range for various plant waxes is ≥5 (refs 8, 9). Also prominent is a complex unresolved mixture (hump) of hydrocarbons centred at the relative retention time of carbon number approximately 19.5. These narrow humps are typically present in degraded detritus of algae and other microorganisms¹⁰⁻¹⁵ and could have such an origin here. An alterative source may be a recycled component of hydrocarbons (both hump and alkanes) eroded from sedimentary outcrops in the regions where the aerosols are generated. Such recycled material has, for example, been reported in recent sediments in a Swiss lake16. An unambiguous origin for the narrow hump in these aerosols can therefore not be assigned, based solely on hydrocarbon data. The isoprenoid alkanes 2,6,10,14tetramethylpentadecane (pristane) and 2,6,10,14-tetramethylhexadecane (phytane) are also present as minor components. The ratio of hump to n-alkanes is low (1.4), confirming a relatively low contribution of anthropogenic organic matter, which would be expected to contribute a high proportion of aromatic and unresolvable materials. Based on GC-MS analyses, the amount of aromatic compounds in this sample is very low. This type of compound distribution is observed for samples 1-4 (Table 1).

Data are also shown (Table 1, samples 5 and 6) for aerosol samples taken on moderately clear days in town and in southwest Jos (at the town limit). These show values for alkane CPI intermediate and ratio of hump to normals equal to those of the samples taken upwind of Jos compared with that taken at Ibadan. This organic matter is probably a mixture of natural and petroleum-derived materials.

In contrast, an aerosol sample collected on a day of moderate visibility in the large city of Ibadan (sample 10) shows a high contribution of petroleum residues. This is indicated by a CPI value of 1.7 and the appearance of a new hump of hydrocarbons centred at the relative retention time of carbon number approximately 28.5 (Table 1, Fig. 2b). The ratio of hump to n-alkanes is high (4.3). CPI values typical for petroleum are ~ 1.0 and ratios of unresolved (hump) to resolved components are high 6.17 The petroleum origin has been further confirmed by GC-MS analyses, which demonstrated the presence of the characteristic molecular markers⁶. Gas chromatograms of hydrocarbon fractions of vehicle exhaust emissions show unresolved humps centred at the relative retention time of the carbon number range C₂₄-C₂₈ (refs 6, 9, and B.R.T.S. unpublished data). This type of contamination is also observed for samples 5 and 6 in Jos and Maiduguri (number 9, Table 1).

Normal fatty acids are present in all samples (80-1,000 ng m⁻³) and exhibit a high even-to-odd carbon number

Carbon preference index, summed from C25 to C34, odd divided by even,

predominance (CPI = 4-11) with maxima at C_{16} , C_{26} and C_{28} , typical of plant waxes and other biogenic sources¹⁸. Minor amounts of anteiso-fatty acids (C₁₃-C₁₇) and traces of iso-fatty acids are part of the fraction. They are commonly found in microbial lipids¹⁹, further supporting a possible recent biological origin for the hump in the hydrocarbon fraction. Normal fatty alcohols are also present in all samples (230-3,000 ng m⁻³) and exhibit a high even-to-odd carbon number predominance (CPI = 4-11) and maxima at C_{28} and/or C_{30} , again typical of plant waxes and other minor biogenic sources¹⁸. These compounds are not found in petroleum with these distributions and concentrations.

We believe that the samples of Harmattan aerosols collected upwind of Jos, Kano and Sokoto contain largely natural organic matter carried with the dusts or adsorbed on the particulates. The lipid material is composed of primarily plant waxes and secondary compounds derived from degraded microbiological detritus (probably mainly of algae) and/or possibly from eroded sedimentary organic matter. In a study of Harmattan dust

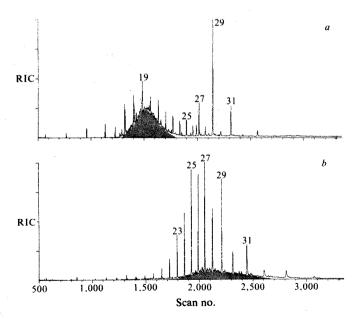

Fig. 2 Examples of total ion current traces from the GC-MS analyses of hydrocarbon fractions. (Numbers over the peaks refer to their respective carbon number.) a, Jos, upwind and b, Ibadan, urban.

deposition in Nigeria, remobilization of existing dust has been invoked to explain a lack of correlation of dust deposition which visibility and solar radiation in the latter half of the season²⁰. Our samples were collected mainly during the latter half of the dust seasons. The lipid material in our samples may arise predominantly in the Sahara like the dust itself. An alternative and more likely explanation is that the lipids originate predominantly in more fertile areas of Chad and Nigeria downwind of the source. Plant wax lipids could be released by a sand blasting effect of the dust on plant surfaces, while the minor microbial detritus could arise by the remobilization of dust from dried-up wadis and lakes, with a possible eroded sedimentary component.

Further such analyses will permit the tracking of aerosol parcels by their lipid signature back to their respective source regions, and will complement the corresponding mineralogical characteristics.

We thank Dr. C. Ekweozor for assistance with sampling in Ibadan, Dr Leon C. Jacobson for assistance with sampling in Maiduguri and Mr E. Ruth for GC-MS data. We also thank the NSF, Atmospheric Research Section (grant no. ATM 79-08645) for financial support.

Temperature of egg incubation determines sex in Alligator mississippiensis

Mark W. J. Ferguson

Anatomy Department, The Queen's University of Belfast, Medical Biology Centre, 97 Lisburn Road, Belfast BT9 7BL, UK

Ted Joanen

Louisiana Wildlife and Fisheries Commission, Rockefeller Wildlife Refuge, Grand Chenier, Louisiana 70643, USA

The factors controlling sexual differentiation in crocodilians are unknown, but heteromorphic sex chromosomes are absent from all species1. Nichols and Chabreck2 speculated that the sex of Alligator mississippiensis was not rigidly determined at the time of hatching but could be influenced by the post-hatching environment. They presented little evidence to support their hypothesis3 (no histological sections of hatchling gonads, no indication of the sex ratio at hatching), and their study failed to take account of habitat preferences of adult male and female alligators4. Here we demonstrate by laboratory and field experiments, that in A. mississippiensis: (1) Sex is fully determined at the time of hatching and naturally irreversible thereafter, and depends on the temperature of egg incubation, temperatures ≤30 °C producing all females, ≥34 °C yielding all males. (2) The temperature-sensitive period is between 7 and 21 days of incubation. (3) Natural nests constructed on levées are hotter (34 °C) than those constructed on wet marsh (30 °C), thus the former hatch males and the latter females. (4) The natural sex ratio at hatching is five females to 1 male. (5) Females hatched from eggs incubated at 30 °C weigh significantly more than males hatched from eggs incubated at 34 °C. This weight difference constitutes a possible selective evolutionary advantage of temperature-dependent sex determination (TSD) in alligators in that females become large and sexually mature as early as possible. The occurrence of TSD in alligators has wide-ranging implications for embryological, teratological, molecular, evolutionary, conservation and farming studies as well as for theories relating to the extinction of other Archosaurs.

Laboratory studies⁵⁻¹⁰ have indicated that in five families of turtles and two of lizards, the temperature of egg incubation affects the sex ratio of hatchlings. Only one study^{5,6} has investigated the effects of natural nest temperatures on sex determination in turtles, and even this involved the construction of artificial nests. There has been no demonstration of a selective evolutionary advantage for the occurrence of TSD in reptiles^{5,6}. Theoretically, such putative selective advantages could be considered within the framework of the Charnov-Bull model^{5,6,11,12}, which has not been experimentally confirmed in higher vertebrates. This model suggests that there is an advantage in allowing the sex of an embryo to respond to its immediate environment, that is, that hatchlings from a cold nest could become either good females or sub-standard males (or vice versa) and that the opposite is true for warm nests.

Alligator eggs (500) were removed from wild nests (Fig. 1) in the Louisiana swamps within 12 hours of egg laying. Only banded³ eggs, laid by middle-aged females, were used in laboratory experiments. These eggs have high fertility, a low spontaneous malformation rate and are homogeneous with respect to egg length, width and initial weight³ (see Table 2). Eggs were randomly placed in one of six groups and incubated (in nesting media³) at 26, 28, 30, 32, 34 or 36 °C, in water-jacketed, air circulating incubators at 100% humidity (Table 1). Eggs incubated below 26 °C or above 36 °C died. After 60 days incubation

(the normal incubation period is 65 days), all eggs were killed and the enclosed alligators fixed in 10% formal saline. Using a dissecting microscope, we noted the presence or absence of oviducts or vas deferens, and the surface appearance of the gonads. The entire reproductive systems of all animals were excised, serially sectioned (8 μm) in the transverse, sagittal and horizontal planes and stained with haematoxylin and eosin, periodic acid Schiff and haematoxylin, Mallory and Weigert Van Gieson. Hatchling gonads were histologically differentiated into ovaries or testes and showed no evidence of bisexuality or hermaphroditism. Sex is evidently fully determined by the time of hatching. Moreover, alligators raised for 1 year in a variety of conditions showed no signs of sex reversal and no evidence of bisexuality. In all experiments, sex was determined macroscopically as well as by serial histological sectioning.

All eggs incubated at ≤30 °C developed into females, whereas all those incubated at ≥34 °C developed into males (Table 1); eggs incubated at 32 °C had a sex ratio of 86.7%:13.3% females to males. There was no significant difference in embryonic mortality between eggs incubated at 28 °C, 30 °C, 32 °C or 34 °C (Table 1). Even if all the dead embryos had been of opposite sex to those that were living,

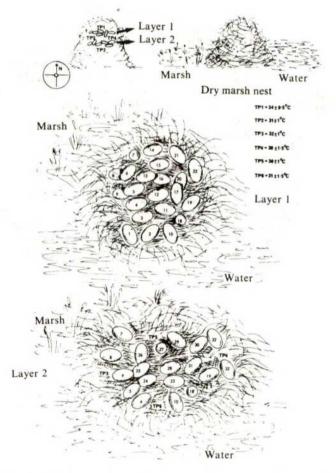

Fig. 1 Map showing the location of eggs and temperature probes TP1-TP6 in a dry marsh nest of A. mississippiensis. The nest consists of a mound of vegetation (mostly Spartina patens) and is ~4 ft in diameter and 3 ft high. Average temperature recorded by TP1 was 34 ± 0.5 °C, and for TP2-TP6, 31 ± 1 °C. Eggs 12, 13 and 16 contained male alligators (average intact weight of hatchlings = 37.5 ± 0.5 g, average weight of hatchling minus yolk = 28.8 ± 0.3 g, average weight of yolks = 8.5 ± 0.5 g); eggs 4-6, 8, 9, 14, 15, 20, 21, 25 and 27-31 contained female alligators (average intact weight of hatchlings = 39.1 ± 2.8 g, average weight of hatchling minus yolk = 28.7 ± 0.5 g, average weight of hatchling minus yolk = 28.7 ± 4.4 g, average weight of hatchling minus yolk = 28.7 ± 4.4 g, average weight of yolk = 10.7 ± 1.4 g); and eggs 1-3, 7, 10, 11, 17-19, 22-24, 26 and 32 were infertile, dead or malformed. The small size of these eggs indicated that they had been laid by a young female³.

Table 1 Sex and mortality of alligators removed after 60 days from eggs artificially incubated at varying temperatures

			Temperature of egg	incubation (±0.2 °C)	4 . 58.454
	26 °C	28 °C	30 °C	32 °C	34 °C	36 °C
No. of eggs No. of dead embryos (% of total)	50 40 (80)	100 4 (4)	100 3 (3)	100 2 (2)	100 6 (6)	50 43 (86)
Females % Of total eggs % Of living eggs	20* 100*	96* 100*	97 100	85 86.7	0 0	0
Males % Of total eggs % Of living eggs	0	0	0	13 13.3	94 100	14 100

All eggs were recovered from wild nests within 10 h of laying, and all were laid by middle-aged female alligators3. Infertile eggs were excluded and the average

egg weights at the start of incubation were statistically similar in all temperature groups (Table 2).

* These animals were developmentally retarded and still exhibited yolk external to the body wall. They were at a stage of embryonic development equivalent to day 48 embryos incubated at 32 °C. Thus they were excluded from the weighing analyses in Table 2.

the differences between the temperature groups would still be highly significant (Table 1). Thus, the temperature of egg incubation determines the sex of A. mississippiensis in laboratory experiments.

To determine the temperature-sensitive period during egg incubation critical for sex determination, eight groups each consisting of 20 eggs were incubated first at 30 °C and then switched to 34 °C after 1, 2, 3, 4, 5, 6, 7 and 8 weeks respectively. A comparable series commenced incubation at 34 °C and were switched to 30 °C. We found that sex was determined by the incubation temperature during weeks 2 and 3; thereafter changes in incubation temperature had no effect. It was easier to produce females, particularly during week 3 of switches from 30 °C to 34 °C. The temperature-sensitive period for alligators occurs much earlier than for other reptiles⁵⁻¹⁰, but alligator eggs are laid at an advanced embryonic stage³, so that the embryonic stages during which sex is determined are comparable. Again there was no evidence of sex reversal, rather the embryos showed progressive gonadal differentiation and were committed to a particular phenotype after the temperaturesensitive period.

Although we have shown that constant incubation temperatures determine sex in laboratory experiments, they may not do so in nature where nest temperatures fluctuate depending on the geographical location of the nest (levée, wet or dry marsh, shaded, exposed), the prevailing climate and whether embryos have a genetic disposition towards one sex^{5,6}. To investigate the role of temperature on sex determination in nature, we placed temperature probes (Taylor Instruments) connected to continuous chart recorders, in different locations (top, bottom and four sides of the egg cavity) within six typical wild alligator nests (see Fig. 1). Two nests were on dry levées, two on wet marsh and two on dry marsh. The natural nest construction was not disturbed during insertion of the probes. Temperatures were recorded throughout the incubation period. After 60 days of incubation, nests were opened, the eggs counted and an accurate nest map drawn, to indicate the positions of the eggs and temperature probes (Fig. 1). All eggs were opened and the alligators coded, fixed and sexed. Sex of the animal was correlated with position in the nest and nest temperature. The average temperature of dry levée nests was 34 ± 0.7 °C at the periphery and bottom of the nests (TP2-TP6, Fig. 1) and 35 ± 1 °C at the top centre of the nests (TP1, Fig. 1): 99% of living eggs (n = 59) were males. The average temperature of wet marsh nests was 29 ± 1 °C at the periphery and bottom of the nests and 30 ± 1 °C at the top centre of the nests: all living eggs (n = 61) were females. The average temperature of dry marsh nests was 31 ± 1 °C at the periphery and bottom of the nests and 34 ± 1 °C at the top centre (Fig. 1). Males hatched from eggs at the top centre of these nests and females from eggs at the periphery and bottom of the nests (Fig. 1). The average sex ratio for dry marsh nests was 5:1, females to males (n = 63). Evidently, sex is determined by egg incubation temperatures in nature as well as in laboratory experiments.

It has been argued^{5,6} that genotypic and environmental sex determination could co-exist if animals had a weak sex-determining locus which operated in most environmental conditions, but which was overridden in extreme conditions. Predictions from Bull's model^{5,6} show that if genotype and temperature both determine sex, then a sex ratio of 1:1 should exist in the hatchling population (but not necessarily in the adult population where differential sexual mortality may occur). To determine the sex ratio at hatching in a wild alligator population, we collected eggs (8,000) from all alligator nests laid within a large area (~2,000 acres) of typical habitat (including levées and marsh) in the Rockefeller Wildlife Refuge, Louisiana. These eggs were collected after 5 weeks of incubation, after the temperature-sensitive period and before maximum egg predation by racoons⁴. They were artificially incubated in nesting media³ at 32 °C, allowed to hatch, raised in controlled environmental chambers and sexed externally at 1.5 yr old (we did not feel justified in killing 8,000 alligator hatchlings for microscopic sexing). As the sex ratio at hatching may vary from year to year, depending on climatic conditions, the above protocol was performed during 1978-81. The average sex ratio for the 4 years was $5 \pm 0.7:1$, females to males. This is consistent with field observations (marsh nests are more numerous than levée nests) and with laboratory experiments, in which viable females are produced over a greater temperature range (28-32 °C) than males (34 °C). This heavily biased female sex ratio means that classical genotypic mechanisms probably have no role in alligator sex determination^{5,6}; but it also presents a problem for sex ratio theory. Fisher¹³ noted that selection within random-mating populations favours a primary sex ratio of 1:1, provided sons and daughters are equally costly to produce. Such a 1:1 result does not necessarily apply to TSD¹⁴, but even using Bull's theory, it is difficult to account for the extreme sex ratio observed in alligators. Therefore, either the present sex ratio is a recent development, perhaps resulting from changes in the availability of various nest sites, or some property of population structure or inheritance is peculiar and selects for the observed sex ratio.

We investigated possible selective advantages for the evolution of TSD in alligators. During incubation, yolk and albumen are progressively used for embryonic growth and metabolism¹ Alligators hatch with a considerable volume of absorbed abdominal yolk which serves as a food source for the posthatching period^{3,4}. As the rate of metabolism of poikilotherms, for example, alligators, depends on temperature 16, we investigated whether there was any weight difference between male and female hatchlings incubated at 34, 32 or 30 °C both in the laboratory (Table 2) and in the field (Fig. 1). Since the size of any hatchling is related to the freshly laid egg weight³, the latter was controlled so that there were no significant differences between the temperature groups at the start of the experiment (Tables 1, 2). It was impossible, however, to control freshly laid egg weight in the nest map field experiments (Fig. 1), as this would have meant disrupting the nests. In laboratory experiments females hatched at 30 °C weighed significantly more than males hatched at 34 °C (Table 2). This weight difference is due to the females having significantly more absorbed yolk than the males (Table 2), which is consistent with the postulated lower rate of embryonic metabolism at 30 °C. As all eggs were incubated at 100% humidity, the latter is unlikely

Table 2 Statistical analysis of the weights of day 60 alligator embryos (hatchlings) and their absorbed yolks as a function of egg incubation temperature and sex

Temperature of egg incubation (±0 2 °C)	No. of eggs	Sex of hatchling	Initial weigh		Weight of hatchl		Weight of minus y		weight o	f yolk (g)
30 °C 34 °C	97 94	Female Male	65.1 ± 5.7 66 2±6 1	P>02	47 6±3.1 43 7±4 0	P<0.001	37 8±3.9 38.2±4.6	P > 0.5	8 1±2.2 5.3±1 9	P < 0.001
32 ℃ 32 ℃	85 13	Female Male	65.8±68		46 2±4 5 45.8±3 9	P>0.7	36.8±4.2 37 0±4 0	P>0.8	7.7 ± 2.5 7.6 ± 2.8	P>09

The initial egg weights were similar in all temperature groups, although in the 32 °C group it was clearly impossible to determine at the onset of the experiment which eggs would become males and which females. The hatchlings were fixed and weighed intact (minus extra-embryonic membranes) to the nearest 0 2 g. The absorbed yolk was then carefully dissected out of the abdomen and both it and the devolked hatchling weighed separately, to the nearest 0.2 g Frequently the sum of the last two weights did not correspond exactly to the first weight due to very small losses of blood. Statistical comparison of any two means was calculated using the t-test18 Values are the mean ± s d.

Table 3 Length and weight of 1-yr-old female and male alligators hatched from eggs incubated at 30 °C and 34 °C respectively

Sex	No of animals	Total len	gth (cm)	Weigh	t (g)
Female	12	63.25 ± 2.54	·	708 3±78.5	
Male	ncubation) 4 ncubation)	53 34±4 83		475±108.5	P<0 001

The alligators were reared after hatching in artificial environmental chambers in identical conditions of, for example, temperature, food, light, water, exercise Values shown are the mean ± s.d. The means for the two groups were compared using Student's t-test18. Total length was measured from the snout tip to the end

to be important¹⁵, although decreased humidity could be associated with increased nest temperatures in the wild. Similar trends were observed in the field—levée nests produced lighter males, wet marsh nests heavier females. Moreover, in a single dry marsh nest, where the initial egg weights were similar, males hatched significantly lighter than females (Fig. 1).

The sexual difference in hatchling size and weight was maintained during the first year of life in alligators raised in environmental chambers4 in identical post-hatching conditions (Table 3). However, once alligators reach a length of ~1 m (at 2-3 yr old) the growth rate of females declines faster than that of males¹⁷. Thereafter, males grow faster and for a longer time than females¹⁷, probably as a result of their differing endocrinology. Sexual maturity in alligators depends on size, both sexes maturing when ~1.8 m long. Because of the initial heavy hatchling weight, and resultant rapid early growth, females become sexually mature either before, or at the same age, as males. The number of years of functional reproductive activity in females is about one-half that of males³. In addition, over 50% of the eggs laid by small (young) females are either infertile or malformed³, while social order favours breeding of larger females before smaller ones. These data, combined with the fact that one male can fertilize several females in any breeding season, make it highly desirable that female alligators should become large and sexually mature as quickly as possible. We suggest that this is a possible selective advantage for TSD in alligators. Thus, animals incubated at the low temperatures which produce females hatch with more energy reserves (absorbed yolk), develop, grow and become sexually mature faster than those incubated at the higher temperatures, which yield males (Tables 2, 3). If genotypic mechanisms determined sex, then the latter would be unrelated to incubation temperature and thus hatchling weight, so that 50% of the offspring would be light females. These animals would mature more slowly, enter the breeding population much later and contribute fewer offspring per lifetime than their heavier counterparts. In terms of the Charnov-Bull model^{11,12}, if the hatchling is light, there is a selective advantage in it being an average male, rather than a below average female. Temperature-dependent sex determination allows expression of this advantage by closely associating hatchling weight with sex. Depending on the life history of other reptiles, there may be selective advantages in being either a light or heavy female or male which could explain why low

temperatures produce females in lizards and males in turtles⁵⁻¹⁰. Interestingly, if alligator eggs are incubated at 32 °C there is no difference in the weights of the resulting male and female hatchlings; both follow the heavier 30 °C female pattern (Table 2). Perhaps the heavy males hatching at this temperature become the large males in the adult population.

Male and female alligators occupy different micro-habitats after hatching: males inhabit open water canals beside levées and females the marsh⁴. Additional selective advantages, for example in terms of predation, may accrue from being a larger, faster growing female in the marsh or a smaller male in the open water. Interestingly, the habitat of adult male and female alligators is closely related to the geographical location of maleand female-producing nests (the former on levées beside open canals, the latter in the marsh). This may represent another selective advantage for TSD because neither male nor female hatchlings have to move great distances (when they would be subject to predation) from 'unsuitable' nesting sites to the preferred adult habitat.

By exploiting TSD to control the sex of alligator embryos experimentally, it is possible to study sexual differences in early embryogenesis as well as differences in the metabolism and action of teratogens³. In addition, TSD has wide implications for habitat planning in conservation studies and for pen design, egg collection times and artificial incubation temperatures in alligator farming. Moreover, if other ancient Archosaurs, for example, dinosaurs, also showed TSD with perhaps a different male-female threshold temperature, then this may explain the selective extinction of these groups in response to a relatively sudden, continuous change in climate to one that is either hotter or colder³.

We thank L. McNease and staff of the Rockefeller Wildlife Refuge for assistance with egg collection, J. Bull for valuable discussion and N. Steinberger for access to preliminary data, obtained by the late C. L. Yntema, which confirm our findings. This work was supported by MRC Grants G979/386/C and 8113610CB, grant EP109/74/75 from the Northern Ireland Eastern Health & Social Services Board, a research travel grant from the Wellcome Trust of Great Britain, a Dixon Research Scholarship from the Queen's University of Belfast, and a Churchill Fellowship, all awarded to M.W.J.F.

Effect of adh genotype and heat stress on alcohol tolerance in Drosophila melanogaster

B. Sampsell & S. Sims

Department of Biological Sciences, Chicago State University, Chicago, Illinois 60628, USA

The alcohol dehydrogenase locus (adh) is polymorphic in most natural populations of Drosophila melanogaster1-11. Eight alleles have been identified on the basis of allozyme electrophoretic mobility and thermostability; two of these, adh Fm and adh Sm , generally have combined frequencies of $\geq 90\%$. In four widely separate locations these major alleles display a clinal change in frequency, that of adh Fm increasing with latitude and altitude^{3-6,11}. Biochemical studies have shown that the Fm allozyme (ADHFm) is more active, but less heat-resistant, than ADHsm(refs 12-14). The fact that these differences are associated with the geographical distribution of the alleles suggests that environmental temperature may be a selective factor in maintaining this polymorphism. We have investigated the effect of high temperature on flies having ADH allozymes with a range of thermostabilities and report here that flies which have relatively labile enzymes show reduced survival on alcoholsupplemented food compared with flies possessing more heatresistant allozymes.

The specific physiological role of ADH has been much debated, but as the results of numerous experiments indicate that alcohol tolerance is a function of overall ADH activity levels 15-20, the enzyme is thought to contribute to the flies' ability to feed and breed in fermenting fruits. The relatively low temperature at which ADH can be inactivated in vitro (40-43 °C)^{5,7,14} suggests that a similar effect could be produced in living flies encountering these temperatures, for example while feeding on fallen fruits warmed by the sun or by heat of fermentation. As ADH is necessary for survival on alcoholic media, alcohol tolerance should be reduced if a significant portion of a fly's ADH is denatured by non-lethal heat exposure. Under such heat and alcohol stress, the relative thermostabilities of different allozymes may have adaptive significance.

In designing an experiment to test this hypothesis, it was desirable to eliminate, as far as possible, the effects of other loci which might alter ADH activity. We therefore used a breeding scheme designed to derive five strains, each homozygous for a different adh allele, but with nearly uniform genetic backgrounds. By using laboratory stocks with various visible mutations and cross-over suppressors, strains were developed which differ only in a small region (about six map units long) surrounding the adh locus (II, 50.1). The strains all have an unmarked X chromosome derived from the Cy/Pm, D/Sb marker stock (stock 97; Amherst, Massachusetts); second chromosomes in which both ends (from 0 to 48.5⁺ and from 51.5⁺ to 108) came from marker stock P232 (Pasadena, California); and third chromosomes obtained from a male caught in the wild. The fourth chromosome was uncontrolled. A sixth stock was not involved in the breeding scheme; this stock was obtained from Davis, California (stock R 72) and carries adh F

(strain 1 in Fig. 1). Allozyme and allele symbols are based on the electrophoretic mobility and thermostability of the enzyme: Fr, fast mobility, heat-resistant; Fm, fast mobility, moderately heat-sensitive; Fs, fast mobility, heat-sensitive; Sm, slow mobility, moderately heat-resistant; Ss, slow mobility, heat-sensitive.

Male flies from uncrowded culture vials were collected soon after eclosion and aged for 5 days on unsupplemented instant Drosophila medium at 23 °C. For the heat treatments, flies were placed in empty, cotton-stoppered shell vials containing a piece of moist blotting paper to maintain adequate humidity. Vials were heated for 13 min in a 40 °C water bath. The flies were then allowed to recover in the same vials for ~4 h by which time they were standing or walking around. The treatment period of 13 min was chosen as the longest time for which almost all flies could survive. It was observed that very small flies usually did not recover consciousness. This occurred sporadically in all the strains and did not seem to be genotypespecific. After the recovery period, flies were transferred to vials of instant medium supplemented with various concentrations (by volume) of ethanol. After 2 days the number of live flies was counted to determine percentage survival. Control flies were treated in the same way, but were not heated. Figure 1 compares the survival of heated with untreated flies of each strain; differences between strains are apparent.

The alcohol tolerance of the heat-treated flies was also compared with that of the control flies for each of the six strains by examining the slopes of the regression lines obtained for each treatment (Table 1). The untreated control flies showed no difference among strains in their response to alcohol. Although there was a slight reduction in survival for both 6% and 8% alcohol, this reduction could not be related to variations in the ADH thermostabilities. By contrast, alcohol tolerance was clearly decreased after heat treatment, and the three strains having the most sensitive enzymes, ADHss and ADHss, showed the greatest reduction. That the reduced survival on ethanol was a result of a decrease in ADH activity was confirmed by direct measurements of ADH activity levels in heat-treated flies (Table 2). Spectrophotometric assays revealed that flies with ADHss and ADHss lose nearly 90% of their ADH activity when subjected to 40 °C for 13 min. Flies with ADHFm have about one-third less ADH, but as these flies had the highest initial levels of ADH activity, a substantial amount of enzyme remains effective. Finally, flies with the two most resistant allozymes, ADH^{Fr} and ADHSm, have the same levels of enzyme activity after heat exposure as before. Figure 1 shows that adh^F flies have the same alcohol tolerance regardless of heat stress, in the range of ethanol concentrations used. In the case of adhSm, there was a significant reduction in survival following heat treatments, but the slope of the regression line was not significantly different from that for the controls, indicating that survival on ethanol was not interacting with the heat treatment.

The 95% confidence intervals of the slopes of the regression lines for the heat-treated flies overlap to such an extent that the only strains that are significantly different are adh^{Fr} and adh^{Sm} , compared with the two adh^{Fs} strains. Note, however,

Table 1 Slopes of regression lines for each strain and treatment in Fig. 1

	C	Control	Heat-treated				
		Confidence	95% Confidence

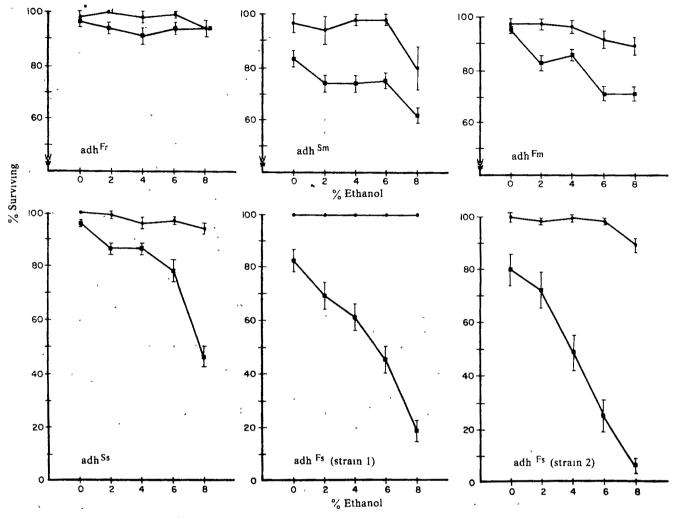

Fig. 1 Relative survival of untreated (control, •) and heat-treated (40 °C, 13 min, •) files on various concentrations of ethanol. Each data point represents the survival of 100-800 files. Bars indicate 95% confidence intervals calculated from the binomial distribution.

that if the strains are ordered by their slopes (indicating interaction of the heat and alcohol stress) the order obtained is exactly the same as the *in vitro* decrease in allozyme thermostability previously reported: Fr>Sm>Fm>Ss>Fs (ref. 21).

Our observations suggest that the variant alleles, adh^{s_i} and adh^{F_i} , may be rare in nature because they are conditionally deleterious or even lethal. Fitness of flies carrying these alleles depends on environmental temperature combined with alcohol concentration.

Other investigators have examined the survival of flies with different adh genotypes following heat shock. Johnson and Powell²² tested flies from four natural populations. In two of the samples, they observed a higher frequency of adh^{8m} among the survivors of a heat shock (40 °C for 30 min) than among a group of untreated flies. No increase in the frequency of either allele was observed in the other two samples. Milkman²³ found no difference in adh frequency between the survivors and non-survivors after heat treatment (40 °C for 10 min). It should be emphasized that Johnson and Powell did not expose their flies, either during or after the heat treatments, to any situation in which ADH is known to be essential.

In our experiments, heat-treated flies with different allozymes showed similar levels of survival in the absence of additional ethanol: $\sim 95\%$ for adh^{Fr} , adh^{Fm} and adh^{Ss} strains, and 82% for adh^{Sm} and adh^{Fs} strains. Only when the food was supplemented with at least 4% ethanol did the survival differences among the strains become significantly correlated with enzyme thermostability. Thus the relevance of Johnson and Powell's results²² to the maintenance of the adh polymorphism is not clear.

A correlation between environmental temperature and adh allele frequency has been observed for the major alleles in Spain⁹, along the eastern coast of the United States²⁴ and in southern Texas and eastern Mexico^{4,6}. The relationship between temperature and fitness however, may not be a simple one. In a more thorough analysis of the north-south clinal variation in a series of Australasian populations, Anderson²⁵ examined the relationship between adh frequency and various environmental variables that change with latitude. He found that differences

Table 2 ADH activity in heat-treated and untreated control flies

		I activity vet weight per min)	
Strain	Untreated controls	Heat-treated (40 °C, 13 min)	% Reduction
adh ^{Fr} adh ^{Fm} adh ^{Fs}	16.6 (0.3) 29.8 (1.3) 19.4 (1.0)	17.1 (0.4) 20.2 (0.1) 2.6 (0.4)	None 32 87
adh Sm adh St	9.8 (0.1) 12.3 (1.5)	10.0 (0.2) 1.5 (0.2)	None 88

ADH activity was measured at 25 °C in a 2 ml reaction mixture containing 2.7 M ethanol and 1 mM NAD in 100 mM Tris-HCl buffer pH 8.6, plus 0.2 ml of crude extract. The extracts were prepared by homogenizing 30 male flies in 1 ml of Tris buffer and centrifuging at 10,000 r.p.m. for 30 min. One unit of ADH activity represents an increase in absorbance of 0.001 at 340 nm. Activities represent the average for two separate groups of flies; standard deviations are shown in parentheses.

in rainfall accounted for 76% of the variation in allele frequency. None of the other variables, including several temperature statistics, could explain the remainder of the variation. He then suggested that temperature and humidity could influence indirectly the adh polymorphism through their effects on such environmental factors as competitor and predator species, types of vegetation available as food sources, varieties of decay-causing bacteria and yeasts, and rates of fermentation and evaporation of metabolic products including ethanol.

It is almost certain that selection acting on the adh locus will involve a complex set of factors and mechanisms. Our results indicate that temperature can, in appropriate conditions, act directly on fitness through the inactivation of heat-sensitive enzymes.

Signal processing times in bacterial chemotaxis

Jeffrey E. Segall, Michael D. Manson* & Howard C. Berg

Division of Biology 216-76, California Institute of Technology, Pasadena, California 91125, USA

The bacterium Escherichia coli responds to changes in the concentrations of various chemicals in its environment¹. A cell swims along a smooth trajectory (runs), moves erratically for a brief time (tumbles) and then runs again, choosing a new direction at random². If a run happens to carry the cell up a gradient of an attractant (such as aspartate, serine and certain sugars), the occupancy of the appropriate chemoreceptor increases with time^{3,4} and a signal is sent to the flagellar motors that increases their counterclockwise bias5. On the average, this extends favourable runs and the cell moves up the gradient. The receptors for aspartate and serine 6-8 are proteins found in the cytoplasmic membrane, known as methyl-accepting chemotaxis proteins^{9,10}, and are the products of the tar and tsr genes¹¹. A cell can adapt to sustained changes of receptor occupancy by carboxymethylating these proteins¹²; it is not known, however, how these proteins signal the flagellar motors or how the signal controls the direction of flagellar rotation. Products of several *che* genes involved in signalling and adaptation have been identified^{13,14}, but with the exception of a methyltransferase¹⁵ (the *cheR* product) and a demethylase¹⁶ (the cheB product), their functions are largely unknown. In an attempt to learn more about the events that trigger a chemotactic response, we have now exposed cells to rapid changes in the concentration of attractants and repellents and measured the time required for flagellar reversal. In wild-type cells and in cells containing a cheR-cheB deletion, the response latency is ~ 0.2 s. In *cheZ* mutants, it is much longer.

Cells were tethered to glass with antibodies directed against flagellar filaments, so that rotation of a cell body could be used to monitor the rotation of a flagellar motor¹⁷. Individual cells were observed with a microscope equipped with an opto-electronic device that provided a continuous readout of the cell's angular position 18,19. A micropipette containing sodium α -methyl-DL-aspartate (α -MeAsp, a non-metabolizable analogue of the attractant aspartate) was positioned with its tip a few micrometres away from the cell, and the cell was stimulated iontophoretically by the passage of current. As the addition of α-MeAsp causes a cell to spin counterclockwise⁵, the current was switched on when the cell changed its direction of rotation from counterclockwise (CCW) to clockwise (CW). We measured the interval of time from the beginning of this stimulus to the next reversal (the response latency), with a resolution of ~ 0.03 s. A typical response is shown in Fig. 1. Stimuli were given about every 30 s, and distributions of interval lengths were constructed (see Fig. 2). The experiments were repeated with different concentrations of α-MeAsp in the pipette and the results are summarized in Table 1. When the concentration in the pipette was ≤0.01 mM, the distributions of interval lengths did not differ significantly from those observed in the absence of a stimulus (Fig. 2a). When the concentration was ≥ 0.1 mM, responses occurred in ~ 0.2 s (Fig. 2b; Table 1). When the concentration was increased by a factor of 100, the mean latency decreased by less than a factor of 2 (Table 1).

To interpret these results, one needs to know the initial concentration of α -MeAsp near a cell and the time course of the change generated by the stimulus. A cell exposed to a step change in concentration of α -MeAsp spins CCW for a time (the transition time) proportional to the change in receptor occupancy. This time is ~180 s for a shift from 0 to 0.16 mM, the apparent dissociation constant of the receptor^{20,21}. The initial concentration of α -MeAsp near a cell was estimated by suddenly bringing the pipette from far away to its final position. No response was detected with ≤ 1 mM α -MeAsp in the pipette. With 10 mM α -MeAsp in the pipette, a transition time of \sim 20 s was observed, corresponding to a jump in concentration at the cell from 0 to \sim 0.008 mM. The maximum concentration change that could be generated by the stimulus was estimated by measuring the transition time after the pipette was in position and the current was switched on and left on. Steady-state concentrations determined in this way are given in the last column of Table 1. Negative ions carried out of the pipette by the current ultimately reach the cell by diffusion. For diffusion from a point source switched on at time t=0 (ref. 22), the concentration at the cell increases as $C = C_{\infty}$ ERFC $[r/(4Dt)^{1/2}]$, where C_{∞} is the steady-state concentration, ERFC is the error function complement, r is the distance between the cell and the tip of the pipette ($\sim 4 \times 10^{-4}$ cm) and D is the diffusion constant of α -MeAsp (8.9×10^{-6} cm² s⁻¹). The concentration rises rapidly, reaching one-third, one-half and twothirds of its steady-state value in 0.01, 0.02 and 0.05 s

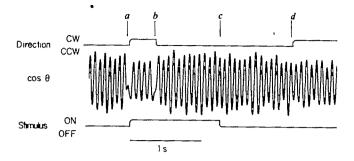

Fig. 1 A strip-chart record of iontophoretic stimulation of tethered E. coli strain AW405. The middle trace shows the cosine of the angle of orientation of the cell, $\cos \theta$; $\sin \theta$ also was recorded (not shown). These two signals were used to generate the event marker shown in the upper trace, which indicates the direction of rotation of the cell. The event marker was updated every time sin $\theta = 0$, that is, twice per cycle, and was used to trigger the stimulus. A second event marker, shown in the lower trace, was turned on when current was injected into the pipette³². The latency was determined by measuring the interval between the onset of the stimulus and the next reversal, as indicated by $\sin \theta$ or $\cos \theta$. The measurement was corrected for the lag in the electronics used to smooth these signals (0.06± 0.02 s). A spontaneous reversal occurred at a. The cell was stimulated 0.03 s after this event was flagged by the upper event marker. Another reversal (the response) occurred at b, 0.34 s later (0.28 s when corrected for lag in the electronics). The stimulus ended at c, and the cell changed direction again at d. Cells were grown as described previously²⁰ on glycerol rather than glucose, washed twice with a tethering medium containing 90 mM NaCl, 10 mM KCl, 10 mM Tris pH 7 0 and 0.1 mM tetraethylenepentamine (tetren³³), resuspended in this medium at one-tenth the original volume, sheared by passage between two syringes equipped with 26-gauge needles and washed once more Then they were tethered, as described previously2 The micropipette (F. Haer 30-31-1 Pyrex 7740 tubing pulled on a D. Kopf 700C puller) was filled with tethering medium containing, in addition, 10 mM sodium α -MeAsp (Sigma) and 0.01 mM ThCl₄ (see below). Its resistance was about 50 M Ω . Connection to the current-injection circuit was made with AgCl-coated Ag wires. The tip of the pipette was positioned 2 μm above a point 4 μm away from the point of attachment of the cell. The stimulus current was -100 nA (negative ions ejected) No positive back current was used. The bath was perfused slowly with tethering medium to prevent any long-term buildup of attractant. The cell was observed with a ×40 water-immersion phase-contrast objective (Zeiss) electrically insulated from the microscope. The experiment was done at room temperature (22±1°C). ThCl₄ was added to the medium in the pipette to neutralize negative charges on the surface of the glass³⁴ which we think were responsible for stimulus artefacts (responses that occurred without any α -MeAsp in the pipette, particularly to the passage of positive currents). As thorium is precipitated by phosphate and chelated by EDTA, these components of the standard tethering medium²⁰ were replaced by Tris and tetren respectively.

respectively. With 0.1 mM α -MeAsp in the pipette, the cells responded on the average in 0.32 s (Table 1), at which time the receptor occupancy was 2.3%. With 1 mM or 10 mM α -MeAsp in the pipette, this change in receptor occupancy should have occurred in 0.002 s or 0.004 s, respectively. The cells responded on the average 0.25 or 0.23 s later, when the changes in receptor occupancy were 10 or 69%, respectively. We conclude that the cells respond with a latency of $\sim 0.2 \text{ s}$ when the change in receptor occupancy is as small as 2% and that larger changes in receptor occupancy do not change the latency much. The latency is well within the upper limit for a chemotactic response time ($\sim 0.7 \text{ s}$) set by the rapid-mixing experiments of Macnab and Koshland³.

The proper functioning of the pipettes (see ref. 23) was checked by replacing the α -MeAsp with 10 mM fluorescein and measuring the fluorescence near the tip of the pipette with a photomultiplier mounted on a dark-field microscope. Changes in fluorescence occurred during the passage of a pulse of negative current on a time scale consistent with that predicted by the diffusion theory to within $\sim 0.01 \, \mathrm{s}$.

We looked for correlations between the mean latency of a cell and the pre-stimulus directional bias of its flagellar motor. In the 34 cells examined, the ranges of mean CW intervals, mean CCW intervals and fractions of time spent CW were 0.34-1.89 s, 0.66-3.12 s and 0.11-0.71, respectively. The mean latencies were not correlated with any of these parameters.

The following controls demonstrated that we were dealing with bona fide chemotactic responses. Wild-type cells (strain AW405) did not respond when the pipette contained only tethering medium (Table 1); they responded to benzoate (100 mM in the pipette) as a repellent, that is, by spinning CW in response to a pulse of negative current. A tar mutant (strain AW539) failed to respond to α -MeAsp but did respond to benzoate as a repellent. A tsr mutant (strain AW518) responded to both α -MeAsp and benzoate as attractants, as expected²⁴. Whenever a response occurred, the latency was \sim 0.2 s.

What steps in the signal-processing pathway cause the latency? Recall that the latency changes very little when the concentration of α -MeAsp is increased by a factor of 100 (Table 1). With large stimuli, more attractant can diffuse to the cell, enter the periplasm and bind to the receptor in a given time, so none of these processes can be limiting. Reactions whose rates are proportional to the amount of bound receptor cannot limit the latency either, because the limit is reached with changes in receptor occupancy as small as 2%. The times required for a small molecule to diffuse from the receptor to the flagellar motor or for an electrogenic impulse to travel along the cytoplasmic membrane are a few milli- or microseconds respectively, so signal transmission per se is not likely to be limiting. Finally, the time required for the flagellar motor to change the direction of rotation of a tethered cell once a reversal is initiated is 0.01 s or less²⁵, so this factor is not important. Either the tar protein activates a sequence of one or more reactions that signal the motor with a delay averaging 0.2 s, or the motor, having received the signal, is not able to initiate a reversal in a shorter time.

The latency of a strain containing a cheR-cheB deletion is normal (strain RP1273)²⁶. Therefore, excitation does not involve methylation¹², demethylation²⁶ or other processes catalysed by the cheR or cheB gene products. The latencies of strains containing cheZ mutations are very long, ~ 2 s (strains RP5006 = cheZ 292, an amber mutant, and RP5007 = cheZ 293, ref. 27). It is known from reversion analysis and interspecies complementation tests that the cheZ gene product interacts with both the demethylase (the cheB gene product) and with components of the flagellar motor involved in controlling the direction of rotation (the cheC = flaA and cheV = flaB

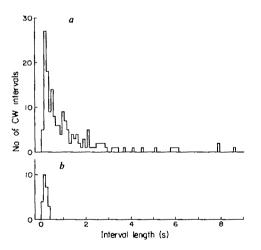

Fig. 2 Distributions of rotation intervals observed before (a) and after (b) iontophoretic stimulation of E, coll strain AW405 (as indicated in Fig. 1). Distribution a includes CW intervals observed immediately preceding each stimulus (3-5) intervals per stimulus, 171 in all, mean \pm s.d. 1.32 ± 1.93 s). Distribution b includes CW intervals observed during each stimulus (1) interval per stimulus, 24 in all, mean \pm s.d. 0.18 ± 0.10 s, corrected for the lag in the electronics). Distribution a is exponential, except for a paucity of intervals of length ≤ 0.1 s; distribution b is bell-shaped. The distribution of CCW intervals observed immediately preceding each stimulus (not shown, 179 intervals in all, mean \pm s.d. 1.36 ± 1.40 s) was similar to the corresponding distribution of CW intervals (a).

Table 1 Response of the wild-type strain to different concentrations of α -MeAsp

Concentration in	CW int	terval (s)		Total no. of	Steady-state concentration at
pipette (mM)	Before stimulus	During stimulus	No. of cells	stimuli	the cell (mM)*
10	0.89 ± 0.31	0.23 ± 0.07	8	100	0.52
1	0.89 ± 0.50	0.25 ± 0.05	9	173	0.022
0.1	0.90 ± 0.47	0.32 ± 0.09	10	164	0.0044
0.01	1.18 ± 0.34	0.92 ± 0.23	3	26	< 0.0005
0	1.04 ± 0.10	1.00 ± 0.49	3	31	0

Measurements were made as described in Figs 1 and 2 legends, with -100 nA pulses of length 0.3-5 s. Each cell was tested at only one concentration of α -MeAsp in the pipette. Values for the CW interval are the mean and s.d. of the mean intervals for each cell, each cell weighted

* Estimated from the transition time, t, for adaptation to a continuous -100 nA pulse, using the formula C = 0.16 t/(360 - t), where C is in mM, t in s (see Fig. 2 of ref. 20). The fractional change in receptor occupancy is $C/(K_d + C)$, where K_d is the apparent dissociation constant of the receptor.

gene products)28. Our results suggest that the cheZ product lies on the excitation pathway. Alternatively, its binding to the flagellar motor is required for rapid initiation of CCW rotation.

The lack of correlation between latency and the directional bias of the motor observed in wild-type cells also seems to be the case for cells containing cheR-cheB or cheZ mutations. The time required for a cell to adapt to a step change in the concentration of α -MeAsp, however, is strongly correlated with the directional bias of the motor (with the mean CCW interval)29. This implies that the signals involved in excitation and adaptation reach the motor by separate pathways or that the latency is due to a step that occurs after these pathways merge.

Although cheZ mutants generally have abnormally high tumbling rates, cheZ-cheC double mutants exist that fail to move up gradients even though their tumbling rates are normal³⁰. Mutants of this sort may represent a new kind of che phenotype. in which the defect lies in the rates at which cells respond to time-varying stimuli. If the latency of a cell is longer than its mean run length, it will choose a new direction at random before it has had a chance to make the appropriate response.

Why is the latency of wild-type cells as long as 0.2 s? There is no reason, a priori, that the response to a large stimulus could not occur within a few milliseconds. However, a cell must time-average its measurement of receptor occupancy if it is to sense small changes in concentration in the presence of statistical fluctuations. For most of the stimuli encountered in nature, averaging times of hundreds of milliseconds are required³¹ There may never have been any selective pressure for the development of more rapid signal-processing machinery.

We thank Steve Block, Jim Hudspeth, Victor Neher and Bob Smyth for valuable suggestions and Sandy Parkinson for bacterial strains. This work was supported by grant AI16478 from the US NIH.

Low doses of ethanol disrupt sensory responses of brain noradrenergic neurones

Gary Aston-Jones, Stephen L. Foote & Floyd E. Bloom

A. V. Davis Center for Behavioral Neurobiology, The Salk Institute, PO Box 85800, San Diego, California 92138, USA

Ethanol is a widely abused drug which has many behavioural and psychological effects¹. In spite of considerable research¹ the brain mechanisms responsible for these effects are unknown. Previously, it has been proposed that noradrenaline (NA)containing locus coeruleus (LC) neurones, which project throughout the brain^{5,6}, mediate the effects of many abused as well as clinically effective psychoactive agents7,8. Recent studies⁹⁻¹¹ have shown that in freely behaving, undrugged animals, NA-containing LC (NA-LC) neurones exhibit marked, short-latency responses to sensory stimuli of many modalities, perhaps serving to bias brain and behavioural activities towards adaptive responses to phasic, unexpected environmental events. We have now examined the effects of ethanol on these sensory responses of NA-LC neurones. In the present study, anaesthetized animals were used to minimize fluctuations in arousal, providing a more stable baseline for assessing pharmacological effects. A class of NA-LC sensory responses which mimic those observed in unanaesthetized animals was studied. In addition, using antidromic stimulation, we investigated the effects of ethanol on the soma excitability, axonal conduction velocity, and strength of recurrent collateral inhibition of these neurones. We now report that low intoxicating doses of ethanol substantially reduce the magnitude and temporal reliability of sensory-evoked responses in NA-LC neurones, perhaps due in part to enhanced feedback inhibition of these cells.

Action potentials were recorded from single NA-LC neurones using glass micropipettes in anaesthetized, male adult albino rats. Rectal temperature was maintained between 36

and 37 °C using a thermistor-controlled heating pad. The locus coeruleus was approached at a 30° caudo-rostral angle to avoid the overlying transverse sinus. The experimental paradigm consisted of recording at least 3 min of spontaneous discharge, followed by activity during a 1 Hz train of 100 antidromic stimuli to either the medial or lateral neocortex, or to the dorsal noradrenergic bundle. Thirty second later activity was recorded

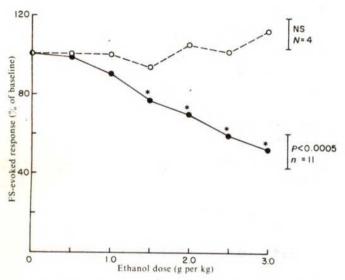

Fig. 1 Effects of ethanol on the magnitudes of FS-evoked response. Response magnitudes are plotted for cumulative doses of ethanol (\bullet) as per cent of baseline (that is, before ethanol treatment) values. Data for similar consecutive trains of FS stimulation without ethanol administration are also shown (\bigcirc). Data from animals anaesthetized with chloral hydrate (n=5) and halothane (n=6) are pooled. NS, no statistically significant effect of stimulation alone on response magnitudes. Bars represent mean \pm s.e.m. and P values are confidence levels resulting from one-way analysis of variance over ethanol doses. *P < 0.005, paired t-tests for each dose compared with baseline.

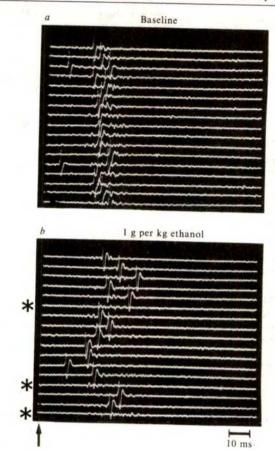

Fig. 2 Effect of ethanol on the latencies of FS-driven spikes. Oscilloscope sweeps triggered consecutively from top to bottom by 1 Hz FS stimuli (arrow) before (a) and 10 min after 1 g per kg ethanol i.p. (b) for the same NA-LC neurone. Note the three sweeps in b that have no spikes (indicated by asterisks) and the increased variability in the latency of FS-driven spikes compared with pre-ethanol activity in a.

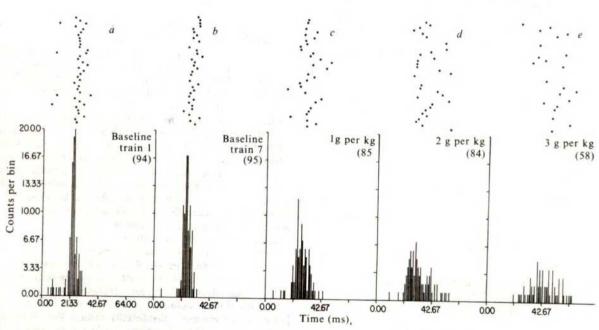

Fig. 3 Post-stimulus time histograms (PSTHs) and raster displays of activity in the same FS-stimulated NA-LC neurone before and after administration of cumulative ethanol doses. a, b, PSTHs for the first and seventh trains of 100 pre-ethanol stimuli and corresponding raster displays for 35 of these stimuli (in consecutive order from top to bottom). c-e, Data following cumulative doses of ethanol, as shown. Numbers in parentheses are the number of FS-driven spikes occurring in each corresponding PSTH. Note that the increased latency variability of FS-driven activity can occur without substantial change in the magnitudes of driven responses (compare c with d). PSTH time bases also apply to corresponding raster displays.

during a similar train at 10 Hz and a subsequent 1 Hz train of 100 electrical stimuli to the contralateral foot (foot-shock, FS). Responses were quantified using computer-generated post-stimulus time histograms (PSTHs)⁹. Response magnitude was defined as the number of spikes within a specified PSTH response interval. After determination of baseline values, 0.5–1.0 g ethanol (12% aqueous solution) per kg was injected intraperitoneally (i.p.), and then the series of tests was repeated. Ethanol injections and test series were made at 10 min intervals, up to a maximum cumulative dose of 3 g per kg. Only one cell per animal was tested with ethanol, and blood ethanol levels were verified at the end of the recording sessions to be appropriate for the injected dose. All recordings were histologically localized to the LC by iontophoresing Pontamine Sky Blue from the tip of the micropipette at the recording site.

Ethanol had no statistically significant effect on the mean spontaneous discharge rate of NA-LC neurones across the entire dose range tested in animals anaesthetized with either chloral hydrate or halothane. Similarly, ethanol had no effect on the ability of 1 Hz antidromic stimulation to elicit soma impulses in these neurones. Pronounced effects of ethanol were seen, however, on the ability of electrical FS stimulation to drive NA-LC neurones orthodromically. As shown in Fig. 1, ethanol decreased in a dose-dependent manner the magnitudes of responses elicited by FS stimuli, an effect observed in each NA-LC neurone tested. Response magnitudes significantly reduced by a lower dose of ethanol (1 g per kg) in chloral hydrate- than in halothane-anaesthetized (1.5 g per kg) animals. The decrease in number of FS-driven spikes was the result of neither repeated trains of FS stimulation nor prolonged anaesthesia (see Fig. 1).

In addition to reducing response magnitudes, ethanol increased substantially the variability of trial-to-trial response latencies exhibited by individual cells (Figs 2, 3). This may be a more profound effect of ethanol on NA-LC neurones than the decrease in response magnitudes, because the standard deviation of response latencies increased to a much greater extent from baseline values (325% after 3 g per kg; see Fig. 4) than the response magnitudes decreased (55% below baseline after 3 g per kg ethanol). In addition, the increase in the standard deviation of latencies was significantly different from baseline at a lower dose of ethanol than was the decrease in response magnitude (compare Figs 1, 4). Thus, the temporal reliability of responses was reduced in a dose-dependent manner for NA-LC neurones after the administration of ethanol, but more markedly and at lower doses than the parallel decreases in response magnitudes. Furthermore, these results for single cells indicate that the temporal coherence (that is, synchronous response activity) characteristic of NA-LC neurones may be markedly reduced by these low doses of ethanol.

A mechanism by which ethanol may exert these effects on NA-LC neurones is suggested by its effects on antidromically elicited activity. Although ethanol had no effect on the number of soma spikes elicited by 1 Hz antidromic stimulation, antidromic soma activation by 10 Hz stimulation and the spontaneous activity which follows antidromic invasion were both reduced by ethanol in a similar dose-dependent manner, to \sim 60 and 70% of baseline, respectively, after 3g per kg ethanol (P < 0.01 and < 0.05, respectively; one-way analysis of variance, n = 5 for all measurements). As both these effects are indices of potency of the recurrent collateral inhibition previously proposed for NA-LC neurones¹², the results indicate that ethanol may increase such recurrent inhibition following activity within the NA-LC. This increased inhibition may partially explain the reduced sensory responsivity we found for these neurones.

In addition we found that ethanol caused a significant dosedependent increase of >8% in the latency of antidromic initial segment spikes in NA-LC neurones during 1 Hz activation. This increased lability in conduction velocity along NA-LC axons seems to enhance the normal variability of conduction

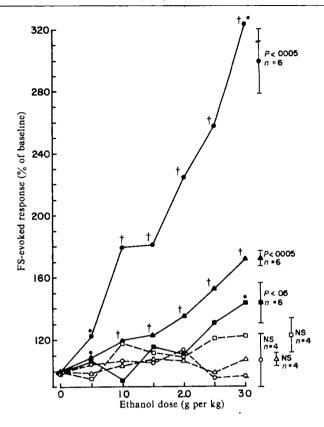

Fig. 4 Effect of cumulative ethanol doses on various measures of FS-driven activity in single NA-LC neurones FS-response latency values. \bullet , s.d. for ethanol treatment; \bigcirc , s.d. for control data (obtained for similar trains of FS stimulation in the absence of ethanol); \blacktriangle , mean for ethanol; \triangle , mean for control; \blacksquare , onset for ethanol; \square , onset for control. Data are expressed as per cent of baseline values. Note that the most substantial effect of ethanol is to increase the variability (expressed here as s.d.) of latency to FS-driven activity, and that there is only minimal effect on onset latencies. Bars represent mean \pm s.e.m. and P values are confidence levels resulting from one-way analysis of variance for dose of ethanol, or for number of stimulus trains in the case of control data. NS, not statistically significant. *P < 0.05; †P < 0.005, paired t-tests for dose or stimulus train compared with baseline data.

velocity during low-frequency impulse activity previously reported for these neurones¹³.

Our results showing decreased sensory responsiveness of NA-LC neurones after low doses of ethanol suggest a new interpretation of previous reports of the effects of ethanol on NA-LC discharge. In one study in paralysed rats14, most LC neurones exhibited decreased activity after a 2 g per kg dose. However, the cells were found to discharge spontaneously at ~17 Hz, much more rapidly than is typical of NA-LC neurones in active animals⁹⁻¹¹ or in anaesthetized rats^{12,13,15-19}. If this elevated activity is due to increased tonic orthodromic input to NA-LC neurones (perhaps as a result of stress induced in paralysed, artificially respired, unanaesthetized animals), then the decreased activity following ethanol administration would be consistent with our results of reduced sensory responsivity in these cells after ethanol. This interpretation agrees with previous results²⁰ in anaesthetized rats, in which more characteristic rates of spontaneous activity for NA-LC neurones were unaffected by ethanol.

In the present studies, quantitatively similar effects of ethanol on NA-LC discharge were observed using either chloral hydrate or halothane anaesthesia; similar results were also observed for three animals anaesthetized with urethane. The fact that these results are reproducible with different anaesthetics indicates that these ethanol effects are not due to an interaction of ethanol

with the anaesthetic and that similar effects may be observed in waking preparations. The fact that doses of ethanol (for example, 3 g per kg) that are greater than those yielding significant reductions in sensory responsiveness in our studies had no effect on the ability of 1 Hz antidromic spikes to invade the soma-dendritic membrane indicate that our results are not due to a general membrane effect on these neurones, such as decreased excitability of NA-LC somata. In addition, previous studies21 indicate that effects of ethanol on peripheral nerve conduction are unlikely to account for our results. The lack of effect on spontaneous discharge rate provides additional evidence that ethanol at these doses is not acting in a nonspecific manner, and also indicates that the increase in intra-coerulear collateral inhibition we propose is not sufficiently intense to alter discharge during spontaneous, unsynchronized activity. Rather, this effect appears to become manifest only when collaterals are synchronously activated, such as during antidromic or sensory stimulation when a large percentage of NA-LC neurones would be engaged simultaneously.

In conclusion, our results demonstrate that low intoxicating doses (0.5-1.0 g per kg) of ethanol produce a marked decrease in the magnitude of sensory-evoked activity in NA-LC neurones and substantially increased variability in the latency of these responses, while also increasing the lability of impulse conduction along their axonal projections. Our results further lead us to hypothesize that ethanol increases the potency of recurrent collateral inhibition within the NA-LC, an effect perhaps responsible in part for the reduced sensory responsiveness of these neurones. We cannot exclude, however, the possibility that ethanol may also decrease the efficacy of excitatory afferents to the locus coeruleus.

Our results suggest a possible mechanism for many of the actions of ethanol on the brain. The diverse efferent system of projections originating from NA-LC neurones^{5,6} and the pronounced effects of NA on locus coeruleus target cells²²⁻²⁵ indicate that a change in the discharge characteristics of NA-LC neurones would have widespread consequences on the central nervous system and on behaviour. Previous studies on the normal discharge properties of NA-LC neurones in behaving animals9-11 have suggested that this system functions to bias the mode of brain information processing and the orientation of behaviour to favour either phasically adaptive responses to unexpected external stimuli or more tonic, vegetative behavioural programmes^{26,27}. Significant disorganization of such a function, an implied action of ethanol in the present studies, may underly the marked disruption by ethanol of adaptive behavioural activity.

Conduction block in the peripheral nervous system in experimental allergic encephalomyelitis

M. P. Pender & T. A. Sears

Sobell Department of Neurophysiology, Institute of Neurology, University of London, Queen Square, London WC1N 3BG, UK

Experimental allergic encephalomyelitis (EAE) has been widely studied as a model of multiple sclerosis, a central nervous system (CNS) disease of unknown actiology. The clinical features of both EAE and multiple sclerosis provide the only guide to the progress and severity of these diseases, and are used to assess the response to treatment. In such comparisons the clinical features of EAE are assumed to be due to lesions in the CNS, but in this disease there is also histological evidence of damage to the peripheral nervous system1-8. However, the functional consequences of such peripheral lesions have been entirely ignored. To examine this we have studied nerve conduction in rabbits with EAE. We report here that most of the large diameter afferent fibres are blocked in the region of the dorsal root ganglion and at the dorsal root entry zone, thus accounting for the loss of tendon jerks and also, through the severe loss of proprioceptive information, the ataxia of these animals. We conclude that whenever clinical comparisons are made between EAE and multiple sclerosis, the pathophysiology associated with the histological damage of the peripheral nervous system must be taken into account.

EAE is a disease induced by inoculating with CNS-derived antigens and adjuvants, and is characterized clinically by limb ataxia and weakness9 and histologically by CNS lesions consisting of meningeal infiltration with mononuclear cells, perivascular cuffing and para-adventitial infiltration with mononuclear cells and perivascular demyelination^{9,10}. This disease has been studied extensively, especially recently in its chronic relapsing form11, because it is widely accepted as an animal model of multiple sclerosis¹². However, it has been assumed that the clinical features of EAE are due to CNS lesions even though histological damage of the peripheral nervous system occurs in many species such as the rabbit^{3,4}, mouse⁵, guinea pig^{1,5} and monkey² and when antigens derived solely from the CNS are used3. It also occurs in rabbits with chronic EAE6, and in guinea pigs⁷ and rats ⁸ with chronic relapsing EAE. Thus, it is possible that the clinical features of EAE are due to lesions of the peripheral rather than the central nervous system. This question needs resolving because the improvement or suppression of the clinical features of EAE by agents such as myelin basic protein¹ and immunosuppressants 14 provides the basis for their use in the treatment of multiple sclerosis.

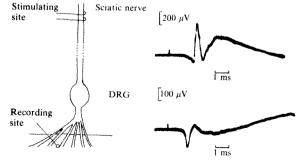

Fig. 1 Recording in the volume conductor over the S1 dorsal root entry zone in response to sciatic nerve stimulation. In each trace, positivity at the active electrode gives a downward deflection. Upper trace, normal rabbit; lower trace, rabbit with EAE. Note the difference in gain. DRG, dorsal root ganglion.

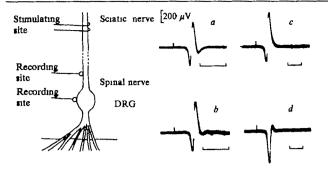

Fig. 2 Recordings in the volume conductor over the spinal nerve and the DRG in response to sciatic nerve stimulation. a, Recording over S1 spinal nerve in normal rabbit. b, Recording over normal S1 DRG. c, Recording over S1 spinal nerve of rabbit with EAE. d, Recording over S1 DRG from the same rabbit with EAE. Time bars, 2 ms.

We have therefore made a clinical, physiological and histological study of EAE in New Zealand white rabbits inoculated intradermally with homogenized rabbit spinal cord and complete Freund's adjuvant. The clinical onset occurred 15-23 days after inoculation and was typical of that previously described', with weight loss, ataxia and weakness of the limbs occurring over 3-4 days. We also examined the tendon jerks and found that these usually disappeared about 2 days after the clinical onset, indicating a lesion interrupting the monosynaptic reflex arc. All the clinical findings could thus be accounted for by lesions in the peripheral nervous system. Histological examination revealed typical, widespread CNS lesions as well as lesions in the dorsal root ganglia and dorsal and ventral roots.

In terminal experiments, 2-6 days after clinical onset, animals were anaesthetized intravenously with 25% urethane, a lumbosacral laminectomy was performed and the left sciatic nerve was exposed in the posterior thigh. The left medial gastrocnemius compound muscle action potential elicited by stimulation of the sciatic nerve in the mid-thigh was normal in all of 12 animals studied.

Conduction into the roots and spinal cord was studied in 10 affected animals. Figure 1 shows typical responses recorded in the volume conductor over the left S1 dorsal root entry zone in response to sciatic nerve stimulation. The upper trace (from a normal control animal) shows a triphasic (positive–negative–positive) wave representing the afferent volley, followed by a longer latency, slow negative wave, the N wave. The initial positive wave is due to the passive outward currents driven by the last activated nodes of Ranvier; the negative phase of the afferent volley is due to the active inward currents occurring during the rising phase of the action potentials and ranges from 300 to $800 \,\mu\text{V}$ in amplitude. The peak-to-peak amplitude of the triphasic wave ranges from $400 \, \text{to} \, 1,000 \, \mu\text{V}$. The N wave is due to the synaptic currents in the second order dorsal horn neurones excited mainly by low threshold cutaneous afferents.

The lower trace in Fig. 1 (from an affected animal) shows three characteristic abnormalities. (1) A very reduced peak-to-peak amplitude (usually <200 μV) indicating that only a small proportion of the large diameter afferent fibres are conducting past the dorsal root ganglion to this point. (2) A very reduced (usually <50 μV) negative wave and a relative increase in the positive wave of the afferent volley, indicating that most of the large diameter fibres still conducting past the ganglion are blocking in the vicinity of the dorsal root entry zone. (3) A delayed peak of the N wave possibly due to conduction persisting in small fibres.

To determine the site of conduction block, volume conductor recordings were made over the spinal nerve and dorsal root ganglion (Fig. 2); traces a and b are are the responses over the normal S1 spinal nerve and S1 dorsal root ganglion, respectively. They are similar and consist of an initial positive wave followed by a larger negative wave. Figure 2c shows a recording

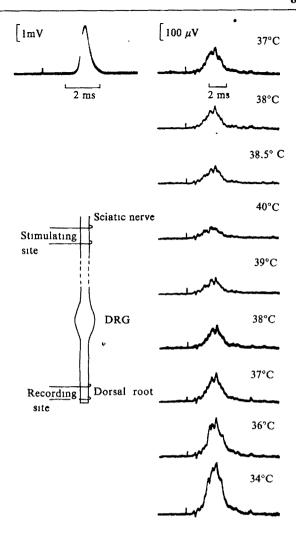

Fig. 3 Monophasic recording from the distal cut end of S1 dorsal root in response to sciatic nerve stimulation. Upper left trace, normal rabbit. Traces on the right are recordings from a rabbit with EAE at various laminectomy pool temperatures, as indicated on the right. Note the difference in gain and time base.

over the S1 spinal nerve of a rabbit with EAE and is normal. The recording in Fig. 2d was obtained over the S1 dorsal root ganglion of the same affected animal and shows a large positive wave followed by a small negative wave, indicating that most of the fibres are blocking at this point.

To investigate the nature of the conduction block, the effects of temperature were studied. Recently, it has been shown 15,16 that in demyelinated single fibres, increasing the temperature within the physiological range produces reversible conduction block, and that in some fibres conduction block can be overcome by reducing the temperature by as little as 0.5 °C. The method used to study the effects of temperature is shown diagrammatically in Fig. 3. The distal cut end of the S1 dorsal root was placed on a pair of electrodes and a monophasic recording made of the compound action potential in response to sciatic nerve stimulation. The upper left trace is from a normal anaesthetized rabbit. The right-hand traces were made at various temperatures of the laminectomy oil pool of a rabbit on the fifth day of clinical disease. On the previous day we increased the body temperature of this animal by 1.5 °C—this caused a reversible increase in ataxia. The response at 37 °C was greatly reduced in amplitude (note the difference in gain) with an area less than 30% of the normal compound action potential, suggesting that most of the large diameter fibres were blocking in

the region of the dorsal root ganglion. The area of the response was progressively reduced as the temperature was increased to 40 °C, which indicates that block was occurring in an increasing number of fibres. When the temperature was reduced to 37 °C, the response regained its original area. On further cooling to 34 °C the area increased by 100%, showing that conduction was restored in a significant number of fibres. These findings strongly suggest that the conduction block is due to demyelination

From our studies we conclude that the loss of tendon jerks and the ataxia of rabbits with EAE can be accounted for by conduction block in most of the large diameter afferent fibres in the region of the dorsal root ganglion and dorsal root entry zone. Such conduction block would mask the clinical expression of any central lesions which alone could produce ataxia. Clearly, these functional considerations must be taken into account when making a clinical comparison between EAE and multiple sclerosis

We thank Drs L. Cuzner and C. Bolton for advice concerning the inoculation procedure. Support from the National Fund for Research into Crippling Diseases and the Brain Research Trust is gratefully acknowledged.

Differences in the kinetics of rod and cone synaptic transmission

Julie L. Schnapf* & David R. Copenhagen

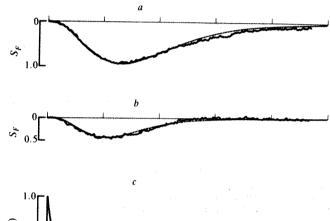

Departments of Ophthalmology and Physiology, University of California, San Francisco, California 94143, USA

Photoreceptors of the vertebrate retina hyperpolarize in response to light. The hyperpolarization elicited by a brief flash is approximately ten times slower in rods than in cones of the same retina1. We have examined the amplification and temporal properties of synaptic transfer of rod and cone signals to a common postsynaptic element, the horizontal cell. We find that the kinetics of signal transfer at these chemical synapses parallels the speed of the light-evoked signals themselves.

Synaptic transfer was studied by recording simultaneously the responses of pre- and postsynaptic cells to dim flashes of light. Eyecups from the snapping turtle (Chelydra serpentina) were prepared as described earlier2. Two intracellular microelectrodes, with tips -100 µm apart in the plane of the retina, were independently lowered into the retina. Intracellular recordings were made from photoreceptors and from axon

terminals of luminosity horizontal cells (HIAT). HIATs receive synaptic input from both rods and red-sensitive cones^{3,4}. Cells were classified on the basis of their receptive field properties and response waveforms, criteria which have been justified with intracellular dye injections^{2,4,5}. Changes in membrane potential were recorded in response to brief (13 ms) flashes of light at a wavelength of 520 or 650 nm. The light intensities used were shown experimentally to be in the linear range¹. Large circular spots of light (1.5-4.3 mm diameter) were utilized in order to eliminate temporal filtering of signals caused by coupling between photoreceptors and between horizontal cells^{6,7} rod-horizontal cell pairs and five cone-horizontal cell pairs were used in this analysis.

Stimulation of cones with bright lights elicited membrane hyperpolarizations in the horizontal cells of up to 40 mV, while rods elicited horizontal cell hyperpolarizations of only a few millivolts. The cone- and rod-mediated inputs to horizontal cells were adequately separated by using stimuli of different wavelengths. The horizontal cell response to dim 520-nm test flashes was mediated solely by rods, as no measurable response in a cone was ever recorded to test flashes of the intensities used to stimulate rod-horizontal cell pairs. Although 650 nm light excited both rods and cones, the faster cone contribution to the horizontal cell response could be clearly separated from that of the rod4. To confirm that the initial part of the 650-nm

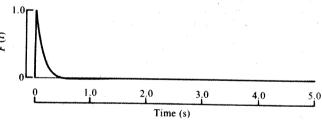

Fig. 1 The rod-horizontal cell synapse. Results from 63 test flashes, 520 nm, presented at t = 0. Two test flash intensities were chosen in order to test for intensity/response linearity. The intensity of the first 30 flashes was 1.0 photon per μm^2 per flash; the intensity of the second 33 was 0.5 photons per μ m² per flash. Stimulus diameter 3.8 mm; S_F , in units of mV per photon per µm² per flash, was obtained by dividing the voltage responses by the flash intensity. a, Ensemble average of light responses of rod. Dashed curve fitted to average is the equation $S_F(t) = A(te/T)^n \exp(-tn/T)$, where A is the sensitivity at the peak of the light response in mV per photon per μ m² per flash, T is the time to the peak of the response in seconds and n is an integer chosen to give the best fit by eye of the experimental data to the curve⁹. In some cases, a non-integer value of n gave a better fit to the rising phase of the light response, but the deconvolution procedure described below requires an integer value. However, the selection of an integer above or below this value has only a small effect on the duration of the calculated impulse response. A = 0.90, T = 1.34 and n = 4. b, Ensemble average of light responses of horizontal cell. Responses recorded simultaneously with rod responses for a above. Dashed curve fitted to average is the same equation as for a, with A = 0.45, T = 1.06 and n = 5. c, Normalized impulse response of rod-horizontal cell synapse. The curve is calculated by deconvolving the equations fitted to the horizontal cell and photoreceptor light responses. The solution to that deconvolution is

$$F(t) = C \exp(-tn_2/T_2) \sum_{k=0}^{n_1+1} t^{(n_2-k)} \frac{(n_1/T_1 - n_2/T_2)^{-k}}{(n_2-k)! \, k! \, (n_1+1-k)!}$$

where C is a constant chosen to normalize F(t) to one at its peak, A, nand T are the constants described above, with subscripts 1 and 2 referring to the values for the photoreceptor and horizontal cell respectively.

^{*} Present address: Department of Neurobiology, Sherman Fairchild Science Building, Stanford University School of Medicine, Stanford, California 94305, USA.

response was not contaminated by rod inputs, the 650-nm test flash was presented on dim red or green backgrounds whose intensities were adjusted for equal cone absorption. In these conditions, cone responses and the early portion of the horizontal cell responses were independent of the wavelength of the background light.

Averaged responses to dim test flashes are shown in Fig. 1 for a rod-horizontal cell pair, and in Fig. 2 for a cone-horizontal cell pair. In all pairs recorded, the response of the photoreceptor peaked after the response of the horizontal cell. On average, the peak of the cone response followed the peak of the conedriven response of the horizontal cell by 8 ms (range 2-18); the peak of the rod response followed that of the rod-driven response of the horizontal cell by 425 ms (range 280-600). The gain of synaptic transfer (the ratio of peak horizontal cell amplitude to peak photoreceptor amplitude) was 5.0 for the horizontal cell-cone pairs (range 2-10) and 0.46 for the horizontal cell-rod pairs (range 0.4-1.2). These values are comparable with those obtained by sequential recording of cones and horizontal cells8, but smaller than the rod-horizontal cell gains previously described4.

To determine how the waveform of the light response of a photoreceptor is transformed during its transfer to the horizontal cell, we calculated the impulse response of the synapse, F(t). This is the calculated form of the voltage response in the horizontal cell for a brief change in voltage in the photoreceptor, and it reflects the rate-limiting steps in synaptic transfer.

Figures 1c and 2c are plots of the normalized impulse response. The method for obtaining this function is described in Fig. 1 legend. The impulse responses of rod and cone synapses are similar in shape and differ only in time scale. The impulse response rises immediately at zero time and slowly relaxes back to baseline with a small undershoot. This waveform is characteristic of a leaky high-pass filter in series with a low-pass filter.

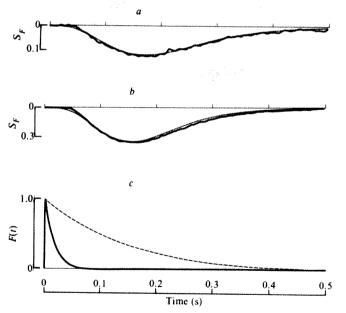

Fig. 2 The cone-horizontal cell synapse. Results from 53 test flashes, 650 nm, presented at t = 0. The intensity of the first 23 flashes was 4.0 photons per µm² per flash, and of the second 30 flashes was 8.9 photons per flash. Stimulus diameter 3 mm, approximately twice the diameter of the receptive field of the horizontal cell. S_F is in units of mV per photon per μ m² per flash. Note that the time scale has been expanded 10 times relative to Fig. 1. a, Ensemble average of light responses of cone. Dashed curve fitted to average is the equation in Fig. 1a legend with A = 0.115, T = 0.174 and n = 5. b, Ensemble average of light response of horizontal cell. Responses were recorded simultaneously with the cone response for a above. Dashed curve fitted to average is the equation in Fig. 1a legend, with A = 0.345, T = 0.156 and n = 6. c, Normalized impulse response of cone-horizontal cell synapse (the smooth curve). The curve is calculated from the equation in Fig. 1c legend using the values given in 2a and 2b as the constants of the equation. For comparison, the impulse response in Fig. 1 of the rod synapse is re-plotted on the faster time scale (---).

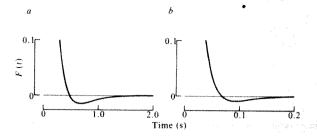

Fig. 3 Undershoot of the impulse response. Portions of the impulse response in Figs 1, 2 are redrawn at higher magnification to illustrate the small undershoot. a Is the impulse of the rod-horizontal cell synapse of Fig. 1, and b is that of the cone-horizontal cell synapse of Fig. 2.

High-pass filtering (or differentiation) is required to account for the faster time to peak of the horizontal cell response relative to the photoreceptor response; the high-pass filtering is also responsible for the negative component of the impulse response which can be seen to dip just below the baseline on the magnified scale in Fig. 3. Low-pass filtering is required to fit the rising phase of the horizontal cell response. At early times the light response of the photoreceptor rises as approximately t^n , while the horizontal cell response rises as t^{n+1} . (Each low-pass stage through which the photoreceptor signal is filtered adds an additional power of t to the rising portion of the horizontal cell response⁹.)

The nature of synaptic filtering is unclear. The high-pass filter stage may reflect time- and voltage-dependent behaviour of the postsynaptic channels 10, postsynaptic 'desensitization' presynaptic depletion of transmitter¹² due to prolonged release. The low-pass filtering stage may represent the finite time that postsynaptic channels are opened by the transmitter released from photoreceptors¹³. In cone-horizontal cell pairs, the lowpass filtering might also simply reflect the filtering of the membrane voltage of the horizontal cell by its membrane time constant¹⁴. The kinetics of transmitter release, degradation and uptake at synapses in other physiological systems are fast relative to channel opening and membrane time constants 13,15, but these processes may be slower at the photoreceptor synapse.

The duration of the synaptic impulse is much greater for the synapse between rods and horizontal cells than between cones and horizontal cells: the impulse response falls to 1/e of its peak value in, on average, 131 ms for the rod synapse (range 100-160) and in 16 ms for the cone synapse (range 12-20). In comparison, in an analysis of the fluctuation of membrane potentials of bipolar cells in the same retina16, the impulse for the cone-bipolar cell synapse was estimated to last ~14 ms in the hyperpolarizing bipolar and ~50 ms in the depolarizing bipolar. A small degree of high-pass filtering was also observed in the bipolar synapses.

The time scale of the synaptic impulse from rod to horizontal cell is approximately 10 times slower than in the conehorizontal cell pair. This difference parallels a difference in the speed of light responses of rods and cones. It was previously suggested that the match between the temporal properties of the light response of photoreceptors and the kinetics of synaptic transmission to ganglion cells might improve the signal-to-noise ratio of transmission in the retina¹⁷. The present experiments demonstrate that this kind of optimization is already apparent at the first synapses of the retina.

Globin structural mutant $\alpha^{125 \text{Leu} \rightarrow \text{Pro}}$ is a novel cause of α -thalassaemia

Michel Goossens*, Kathleen Y. Lee, Stephen A. Liebhaber* & Yuet Wai Kan†

The Howard Hughes Medical Institute Laboratory and the Division of Molecular Hematology, Department of Medicine, University of California, San Francisco, California 94143, USA

The duplicated human α -globin structural loci lie on chromosome 16 and are arranged in the order 5' $\alpha 2-\alpha 1$ 3'. Although the most common molecular mechanism for α -thalassaemia is deletion of segments of DNA that contain one or both of these α -globin structural loci¹, two molecular lesions that are not due to gross gene deletion have been defined. In one, a point mutation in the termination codon of the $\alpha 2$ gene results in the production of an elongated α -globin chain^{2,3}. As only a small amount of the mutant globin chain is produced, α thalassaemia results. The second lesion, which is caused by a 5-base pair (bp) deletion in the first intervening sequence of the α 2 gene, results in abnormal mRNA processing and α globin chain deficiency4. We now describe a novel mechanism for α -thalassaemia not involving deletion. A single nucleotide mutation in the coding region of the $\alpha 2$ gene results in the substitution of proline (Pro) for leucine (Leu) in a region of the H helix of the α -globin chain, which is critical for $\alpha 1-\beta 1$ contact. This probably impedes $\alpha 1-\beta 1$ dimer formation, the initial step of haemoglobin tetramer assembly, and produces an α -thalassaemia phenotype.

The clinical, biochemical and genetic data on a particular patient with haemoglobin-H (Hb-H) disease and his family have been reported in detail elsewhere5. Usually only one of the four α -globin loci remains in Hb-H disease (genotype --/- α); the propositus and his sister, however, have Hb-H disease with both α-globin loci deleted on one chromosome and intact on the other (genotype $--/\alpha\alpha$). The family members who have microcytosis characteristic of α -thalassaemia have two different genotypes: the usual two-gene deletion $(--/\alpha\alpha)$ and an unusual genotype in which all four α -globin genes are intact $(\alpha \alpha / \alpha \alpha)$. To explain the presence of α -thalassaemia trait in members of the latter genotype, we postulated that one of the chromosomes with two intact α -globin genes was defective in α -globin chain production $[\alpha \alpha/(\alpha \alpha)^{T}]$, and that the combination of this nondeletion α -thalassaemia chromosome with the usual two-gene deletion form produced the Hb-H phenotype seen in the propositus and his sister $[--/(\alpha\alpha)^{T}]$.

Previous Southern analysis of the propositus' DNA revealed no abnormalities in the α -globin gene map⁶. mRNA analysis showed an α 1- to α 2-globin mRNA ratio of 2.5:1, which is identical to that found in normal reticulocytes, and indicates that both α -globin genes are active in transcription⁷. To define the molecular lesion producing non-deletion α -thalassaemia, we cloned the segment of his DNA that contained the two α -globin genes. This segment must be derived from the chromo-

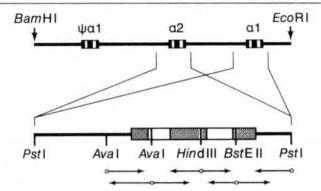

Fig. 1 Diagram showing the DNA segment cloned from the patient with non-deletion Hb-H disease, and the sequencing strategy of the α loci. Leukocyte DNA from the propositus was digested with BamHI and the 14.5-kb fragment isolated by discontinuous electrophoresis on an agarose gel14. The BamHI end was made flush by adding the tetranucleotide GATC with Klenow fragments of DNA polymerase I, and was ligated to an EcoRI . The DNA was then digested with EcoRI and the resultant 13-kb fragment containing the 5' $\psi\alpha$ - α 2 and α 1 3' loci was ligated to Charon 4A arms at the *EcoRI* site. The phage was packaged and used to infect *Escherichia coli* DP50 Sup F¹⁶. Phages containing α -globin inserts were identified by the method of Benton and Davis 17 with 32P-labelled α-globin cDNA, and those with a positive signal were screened twice more. One such isolate, AGL6, was grown in a 11 culture. The phage particle was isolated and banded on a caesium chloride gradient (1.5 g ml⁻¹) in a Ti50 rotor at 30,000 r.p.m. for 20 h. The DNA was then digested with EcoRI and BglII, and two fragments of 9.2 and 3.6 kb, which contained the $\psi\alpha$ - α 2- and α 1-globin loci respectively, were subcloned into the EcoRI-BamHI sites of pBR322. The restriction sites used for sequencing are shown in the lower diagram. Sequencing was performed according to the Maxam and Gilbert method18, and carried out side by side with the corresponding fragments from the normal α -globin loci cloned by Lauer et al.

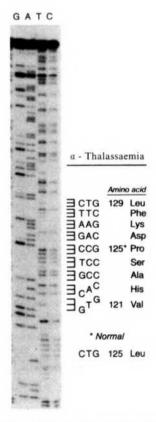

Fig. 2 Sequencing gel of the patient's DNA showing the region of the mutation. The DNA fragment was 5'-labelled at the BstEII site with 32P by polynucleotide kinase, and sequenced by the method of Maxam and Gilbert.

some affected by non-deletion α -thalassaemia, as both α -globin loci are deleted from the other chromosome. We cloned in Charon 4A a 13-kilobase (kb) fragment extending from the BamHI site to the EcoRI site and containing the $\psi \alpha$ -, α 2- and α 1-globin genes. The α 1- and α 2-globin loci were then separately subcloned into pBR322. Both the α 2- and the α 1-globin genes were sequenced side by side with the corresponding α -globin fragments from a previously isolated normal DNA. (See Fig. 1 for details.)

We completely sequenced the $\alpha 1$ and $\alpha 2$ loci, from the AvaI site located 100 nucleotides 5' to the cap site to the PsfI site 90 nucleotides 3' to the poly(A) addition site. The α 1-globin gene sequences from the propositus' DNA were identical with normal α1 sequences. We detected one difference, however, in the coding region of the $\alpha 2$ gene, at the position corresponding to amino acid 125, where the normal leucine codon (CTG) was changed to proline (CCG) (Fig. 2). We were able to confirm this mutation by restriction analysis because it abolished an EcoRI recognition site (CCTGG→CCCGG) and created a new recognition site for the enzymes HpaII and MspI (CCGG). The normal 337-bp MspI fragment that extends from the second intervening sequence to the 3'-noncoding region of the a2globin gene was cleaved into two fragments of 216 and 121 bp in the propositus' DNA. The mutation could potentially be detected in this patient's genomic DNA by methods similar to those used to detect the DdeI polymorphism in sickle cell anaemia8.

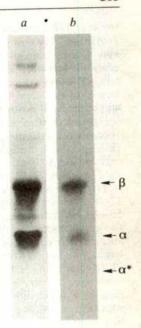

Leu→Pro mutations usually exert a profound effect on the stability of the haemoglobin tetramer. All the known Leu → Pro changes occurring in the α - and β -globin chains produce unstable haemoglobins and cause haemolytic anaemia9. For example, Hb Bibba, an α mutant also located in the H helix $(\alpha^{136\text{Leu} \to \text{Pro}})$, produces an unstable haemoglobin syndrome¹⁰. The unusual feature of the mutation in the family we studied is that the Leu \rightarrow Pro mutation produces α -thalassaemia rather than an unstable haemoglobin. Carriers of this lesion (genotype $\alpha^{125 \text{ Pro}} \alpha / \alpha \alpha$) are phenotypically indistinguishable from carriers of α-thalassaemia trait. The combination of this gene and a deletion α -globin gene $(--/\alpha^{125 \text{ Pro}}\alpha)$ produces the clinical features of Hb-H disease.

A search for the abnormal α-globin chain using electrophoresis on starch gel, Triton-urea gel, and isoelectric focusing was unsuccessful. However, after incubating the patient's reticulocytes with 3H-leucine and separating the haemolysate on a Triton-urea gel, we observed an abnormal radioactive α -globin band that turned over rapidly (Fig. 3). This unstable α -globin could produce Hb-H disease by the following mechanism. Three amino acids ($\alpha^{122\, {
m His}}$, $\alpha^{123\, {
m Ala}}$ and $\alpha^{127\, {
m Lys}}$) in close proximity to $\alpha^{125 \text{ Leu}}$ participate in $\alpha 1-\beta 1$ contact¹¹. The Leu→Pro substitution probably disrupts the H helix and in turn interferes with these contact points. The formation of $\alpha 1 - \beta 1$ dimers may thus be impeded and the ability of the β -chains to form Hb-H (β_4) may exceed that of the abnormal α -chain and the normal β -chain to form $\alpha 1$ - $\beta 1$ dimers. The uncombined α -chains would then be destroyed by proteolysis and an α-thalassaemia-like syndrome would ensue. Such a mechanism is consistent with the normal $\alpha 1$ to $\alpha 2$ ratio found in the propositus7 because the abnormal mechanism operates after translation. In contrast, in all cases of α - and β -thalassaemia produced by abnormal mRNA processing and by early or late termination, mRNA from the affected locus is either decreased or unstable in vivo 4.7,12,13.

In conclusion, we have described a human globin mutation, α 125Leu - Pro, that produces the α-thalassaemia phenotype through a novel post-translational mechanism. As it was the propositus' mother who carried the α -globin mutant, we have named this variant Quong Sze, after the province in China where she was born.

Fig. 3 Electrophoresis of globin on a Triton-urea gel. The reticulocytes from the propositus with Hb-H disease were concentrated by Percoll-Reno M60 gradient²⁰ and incubated with ³H-leucine for 20 min as previously described21. Cells were lysed and 1 µg of haemoglobin was applied to a Triton-urea gel and elec-trophoresed as described earlier22. The gel was stained with Coomassie blue, dried and autoradiographed for 4 weeks. Lane a, Coomassie blue staining of the gel; b, autoradiogram of the gel. The faint radioactive band (α^*) that migrates faster than the normal α -globin band in b has been characterized as the abnormal aglobin by hybrid arrest of translation by α-globin cDNA in a cell-free system (S.A.L. and Y.W.K., unpublished) and work is in progress to assess its synthesis and turnover rates.

Germ-line MuLV reintegrations in AKR/J mice

Winship Herr & Walter Gilbert

Department of Biochemistry and Molecular Biology, Biological Laboratories, Harvard University, Cambridge, Massachusetts 02138, USA

AKR mice are viraemic from birth1 and contract leukaemia at high incidence at 6-9 months of age2. They express, in all tissues studied, the ecotropic (mouse infectious) retrovirus AKV¹. Rowe^{3,4} showed, by crossing AKR mice with the low-viraemia, non-leukaemic NIH/Swiss mice, that viraemia and the leukaemic phenotype are linked and carried at two independent loci (Akv-1 and Akv-2). These two loci were shown to represent integrated ecotropic proviruses5.6. As part of a study of the structure of proviruses which arise in the leukaemic thymus of AKR mice, we identified ecotropic-specific hybridization probes from different regions of the AKV genome7. Initial Southern hybridization⁸ analyses showed that individual leukaemic AKR/Jackson mice, which have been sibling inbred for over 140 generations, had differing numbers of ecotropic proviruses⁹. We now report analyses showing that AKR/J mice had three common proviruses; however, two additional ecotropic loci were scattered throughout the Jackson Laboratory AKR population. These loci probably arose through reinfection of the germ line and represent a currently occurring amplification of ecotropic proviruses in these inbred mice.

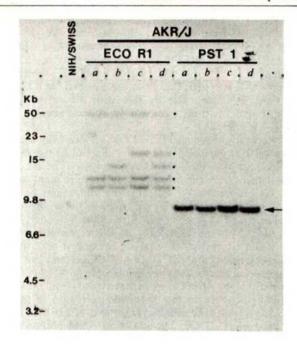

Figure 1 shows a set of four different 'homozygous' hybridization patterns from individual AKR/J mice. The ecotropic virus-specific hybridization probe corresponds to the gp70 region of AKV (Fig. 1). As the AKV genome contains no EcoRI sites⁶, a unique EcoRI fragment, larger than 8.8 kilobases, arises from each integrated AKV provirus. AKR/J mice all carry 50-, 12- and 11-kb ecotropic EcoRI fragments (lanes a-d). The 50-kb EcoRI fragment is the Akv-1 allele6, while the other two are characteristic of the AKR/J substrain6 and have probably been fixed within these AKR mice since the breeding began. In addition to these three loci we observe AKR/J mice which carry a 14- or 17-kb EcoRI fragment (Fig. 1, lanes b, c), some animals carry both proviruses (lane d). We also observe patterns in which either the 14- or 17-kb fragment is heterozygous (appears at one-half intensity, see Fig. 2 as an example). New ecotropic EcoRI fragments have also recently been observed in AKR/J mice by Yoshimura and Breda10.

All five proviral EcoRI restriction fragments seem to contain a full-length AKV or closely related genome. They are larger than 8.8 kb and each hybridizes to the three different ecotropic probes. (Figure 1 shows the three probes on a restriction map of AKV¹¹.) In addition, PstI digestion of each of the four different samples in Fig. 1 (EcoRI lanes a-d) produces a single full-length internal PstI fragment (Fig. 1, PstI lanes a-d), consistent with the restriction map of AKV.

Figure 2 shows that the 14-kb EcoRI ecotropic restriction fragment is inherited in the germ line. A female AKR/Jackson mouse homozygous at all five ecotropic proviral loci was mated with a male AKR/Jackson mouse which lacked the 14-kb proviral EcoRI fragment. EcoRI digestion and Southern blot analysis of the F₁ embryos revealed that the 14-kb fragment was present but at one-half the intensity of the female parent. An analogous experiment showed that the 17-kb fragment is also carried in the germ line (data not shown).

To examine the cellular sequences on each side of the provirus, we used a combination of enzymes, one of which cuts inside the provirus, and a specific probe that lies on a known side of the cut. Figure 3A shows, using the pol probe and a combination of XbaI and EcoRI, that the five 5' sequences are all different. Although the three fixed proviruses generate the same 13-kb XbaI fragment, this is fortuitous, because double digestion with XbaI and EcoRI generates three unique fragments (9.2, 10 and 13 kb), which shows that the EcoRI sites differ. The 17-kb EcoRI fragment generates unique 15-kb XbaI and 10.2-kb EcoRI-XbaI fragments whereas the 14-kb EcoRI locus produces an 11-kb XbaI fragment which contains no EcoRI sites. We also identified the 3' cellular BamHI and SacI sites with the C-p15E and gp70 probes, respectively. Figure 3B summarizes all the data as restriction site maps for the different proviral sites. As it is unlikely that these differences are due to point mutations, because we detect no alterations in the PstI restriction sites within the proviruses (see Fig. 1), we conclude that the cellular sequences around each provirus are different; these new proviruses probably arose through reinfection of germ-line cells and integration at unrelated sites.

We analysed 21 pedigreed mice from the AKR/Jackson pedigree expansion colony in January 1980, to examine the distribution of ecotropic proviruses. Figure 4 shows the relationship between the mice surveyed, outlined as a family tree, and the Southern blot analysis from which we determined whether the mice were heterozygous or homozygous at each locus. The variable bands are more prevalent in this survey than in an original pool of DNA from 20 mice examined in March 1978, when the variable proviruses were present in only 10–20% of the haploid genomes. The 17-kb fragment is present in 22 of

Fig. 1 Individual AKR/J mice, although sibling inbred for over 140 generations, do not carry identical numbers of integrated ecotropic provirus sequences. DNAs from four mice (a, b, c and d) previously identified as exhibiting different homozygous patterns were used in this Southern hybridization. Digestion with EcoRI generates the four different patterns whereas PstI digestion produces the single internal AKV PstI fragment (arrow). The three constant EcoRI fragments are approximately 11, 12 and 50 kb long. The variable proviral EcoRI fragments are 14 kb (lane b) and 17 kb (lane c). Lane d displays all the ecotropic proviral fragments we have detected in AKR/J mice. 10 μ g of purified 15 brain DNA was digested with either EcoRI or PstI. The samples were electrophoresed through a 0.5% agarose gel16 using undigested A phage DNA, A phage DNA digested with HindIII, A phage DNA digested with XhoI, and pBR322 digested with BamHI and Pst1 as size markers. The fractionated DNA was transferred to nitrocellulose filters^{8,17}, hybridized^{17,18} with the gp70 probe, washed¹⁸ and autoradiographed for 10 days with an intensifying screen^{19,20}. A control lane, labelled NIH/Swiss, contained 20 µg of EcoRI digested DNA isolated from the liver of an NIH/Swiss mouse, which does not contain a complete ecotropic provirus21 and shows, as expected, no hybridization. The location of the ecotropic-specific hybridization probes? (black boxes) is shown with respect to a restriction map of the AKV genome¹¹: P, PsrI; B, BamHI; S, Sacl; X, Xbal. The AKV genome contains no EcoRI sites. The long terminal repeats (LTR) are shown as boxes. The probes are single-stranded radiolabelled AKV cDNA restriction fragments7 prepared by the method of D. Schwartz (personal communication). The probes are named according to the gene to which they map. The p15E probe lies within the C-terminal coding region of p15E and is called C-p15E7

the 42 haploid genomes examined and the 14-kb fragment is found in 19. These results are not an average of the entire mouse colony in January 1980, because the mice were selected such that they would be most distant from one another; nonetheless, it is likely that these new proviruses have increased in frequency between the two analyses. The pattern of provirus-containing loci displayed in Fig. 4 indicates that: (1) the common breeding pair at the top of the chart was heterozygous at both loci, (2) there is no obvious linkage relationship between loci and (3) both proviruses probably arose concurrently.

Different AKR substrains carry varying germ-line patterns of ecotropic proviruses in which only the Akv-1 allele is common to all^{6,12}; this suggests that germ-line reintegrations have occurred in these mice and that the original AKR line contained only the Akv-1 locus. Rowe and Kozak¹³ have observed that new virus-inducing loci appear in inbred Akv-1 congeneic mice if the maternal mice are viraemic. These are probably reintegrations of the AKV genome, which suggests that the new loci we

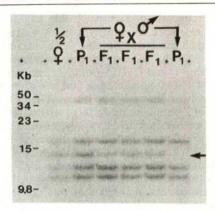

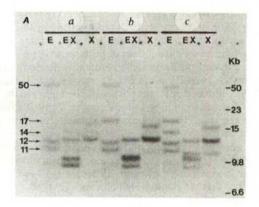

Fig. 2 Southern hybridization analysis of a cross between a male AKR/J mouse lacking the 14-kb proviral EcoRI fragment and a female AKR/J mouse homozygous for this fragment shows that these proviruses are carried in the germ line. The DNA from both parent AKR/J mice was isolated from brain tissue. The F_1 DNA was from 16-day old embryos. In each case, $20\,\mu g$ of EcoRI-digested DNA was loaded in each lane, except the left lane in which only 10 µg of the female parent DNA was loaded. The filters were hybridized with the gp70 probe and autoradiographed for 10 days as described in Fig. 1 legend. The left two lanes contain the female parent DNA, the right lane contains the male parent DNA and the three middle lanes DNA from three individual embryos. The arrow indicates the 14-kb EcoRI fragment which is heterozygous in the embryo genome.

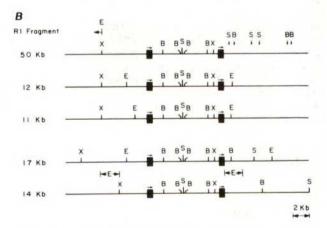

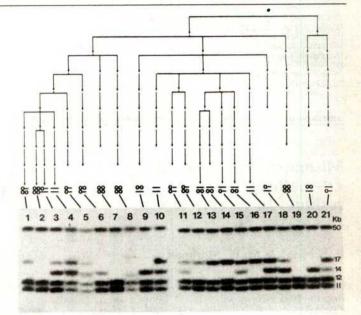

Fig. 3 Digestion of AKR/J DNA with XbaI, which cuts once within the AKV provirus, and EcoRI, shows that the cellular sequences surrounding the ecotropic germ-line proviruses differ. A, Three samples of DNA (10 µg per lane) isolated from the brain tissue of individual AKR/J mice were cut with EcoRI (E) and XbaI (X) or with both enzymes (EX). Sample a contains only the three constant EcoRI fragments, sample b carries in addition the 17-kb EcoRI fragment, and sample c contains all five provirus loci. The filters were hybridized to the pol probe as described in Fig. 1 legend and autoradiographed for 3 days. B, Restriction site maps of the cellular sequences surrounding each of the germ-line AKV proviruses. The provirus sites are from Steffen $et\ al.^{11}$. The $XbaI\ (X)$ and $EcoRI\ (E)$ sites were determined from the data shown in A. The position of the 3' SacI (S) and BamHI (B) sites were determined from similar experiments using the gp70 and C-p15E probes, respectively. We have not discriminated between the 3' cellular BamHI and SacI sites of the three constant proviruses.

Analysis of predigreed mice from the Jackson Laboratory colony reveals the distribution of the variable ecotropic proviruses. A pedigree chart was created for the pedigree expansion colony in January 1980, and 21 mice were selected to represent as wide a population as possible. The origin of each AKR/J mouse is shown in the upper portion of the figure. Each arrow indicates a generation. DNA (20 µg) from each of 21 mice was cut with EcoRI and analysed with the gp70 probe as described in Fig. 1 legend. The interpretation of the autoradiogram is shown schematically above each lane. (0) Signifies the absence and (-) the presence of the variable provirus at a given locus. The filter was autoradiographed for 3 weeks. Samples 4, 5 and 8 contain partial digestion products.

observe in AKR/J mice may arise by reinfection of the embryo

The AKR/J mice seem to be undergoing an amplification of the ecotropic proviruses. Xenotropic viruses might be the result of a past amplification of retroviral genomes. These viruses, which are unable to infect mouse cells but do replicate in cells from other species14, are present in much larger numbers (about 30 proviruses⁷) than the ecotropic proviruses. In a murine ancestor, the 'xenotropic' viruses may have replicated efficiently and amplified their numbers. By natural selection, the murine ancestor may have subsequently become resistant to infection by these viruses, creating a large number of relatively silent endogenous proviruses. Amplification of proviral genomes followed by mutation is one mechanism by which the organism could form a family of related genes, for example, the gp70 family coding for cell-surface markers.

We thank E. Les and Jackson Laboratories for help in screening the AKR/J mouse colony, D. Steffen for the NIH/Swiss DNA, M. Kreitman, N. Lonberg, D. Steffen and R. Weinberg for discussions, and D. Steffen for communicating results before publication. W.H. was supported, in part, by a NSF predoctoral fellowship. This work was supported by NIH grant GM09541-20.

Mismatch correction at O⁶-methylguanine residues in E. coli DNA

P. Karran* & M. G. Marinus†

Escherichia coli has a correction system which removes mismatched bases from DNA1. Mutants (dam) which lack the major DNA adenine methylase² are hypersensitive to the effects of base analogue mutagens such as 2-aminopurine³ and appear to be defective in mismatch correction. Phenotypic revertants of dam mutants to base analogue resistance include second site mutations in mutL or mutS genes4, which are also part of the correction system. We report here that E. coli dam mutants are also sensitive to the DNA methylating agent N-methyl- N^\prime nitro-N-nitrosoguanidine (MNNG), which introduces O6methylguanine (m6G) into the DNA. This sensitivity, however, was not observed using methylating agents which generate only low amounts of this alkylated base. Furthermore, the introduction of either a mutL or a mutS mutation into dam strains abolished the sensitivity to MNNG. These results suggest that mismatch correction occurs at m6G residues in DNA. These lesions miscode in DNA polymerase I-mediated DNA synthesis in vitro⁵ and are known to be mutagenic in vivo⁶. Nevertheless, it appears that mismatch correction at m6G residues in DNA does not lead to reduced induction of mutation by MNNG.

The major repair pathway for the promutagenic base m⁶G in E. coli is via a methyltransferase induced as part of the adaptive response to alkylating agents⁷⁻⁹. The adaptive response is induced by exposure to sublethal concentrations of alkylating agents and renders cells resistant to the lethal and mutagenic effects of subsequent treatment with such agents9. To allow the maximum possible interaction between m⁶G and the mismatch correction system, except when specifically stated, all the experiments reported were performed in conditions in which the adaptive response is not induced. Figure 1a shows that the dam-3 strain GM113 is more sensitive than its parental strain GM112 (dam⁺) to treatment with MNNG for 5 min. For MNNG, a fairly high proportion (7%) of the total alkylation products are m⁶G (ref. 10). To determine whether the sensitivity of dam strains to MNNG is related to the presence of this base, we tested the sensitivity of GM113 (dam-3) to dimethyl sulphate (DMS) for which m⁶G constitutes only a very minor proportion (0.5%) of the total products¹¹. Figure 1b shows that dam strains are not significantly more sensitive to DMS than dam + strains; this agrees with a previous report that dam strains are only slightly hypersensitive to methylmethanesulphonate (MMS)¹² which also induces only a low proportion of m⁶G residues in DNA.

As the introduction of a mutation into any one of several mutator loci abolishes the sensitivity of dam strains to killing by the base analogue 2-aminopurine^{3,4}, we examined the effect on MNNG sensitivity of these second-site mutations. GM150 (mutL-451 dam-3) and GM169 (mutS-453 dam-3) were more resistant to MNNG treatment than GM113 (dam-3) and were similar in sensitivity to wild-type strains (Fig. 1c). By analogy to the effect of 2-aminopurine on these strains, we suggest that dam strains are sensitive to MNNG because of an attempted mismatch correction at base pairs containing m6G. In the absence of the requisite control normally present in wild-type (dam⁺) strains, this leads to cell death in a high proportion of cases. The introduction of the mut loci prevents the occurrence of this abortive correction mechanism, thus restoring wild-type survival levels. A reduction in the amount of m⁶G in dam strains should therefore result in a decreased frequency of these 'death-prone' repair events and thus enhanced survival after MNNG treatment. This reduction in the level of m⁶G may be brought about by pre-adaptation of the cells. Adapted dam strains should show enhanced survival after challenge with MNNG, but Jeggo et al.13 were unable to demonstrate such adaptation of dam strains to MNNG challenge. However, using a slightly different adaptation protocol, we have demonstrated enhanced survival in these strains after MNNG challenge (Fig. 2a). As normal levels of the m⁶G methyltransferase are induced in GM113 (dam-3) after adaptation (Fig. 2b), we conclude that at least part of the observed adaptation for survival in this strain is due to an enhanced removal of m⁶G.

The abolition of sensitivity to 2-aminopurine by the introduction of a second-site mut mutation into dam strains is accompanied by an increased frequency of both spontaneous and base analogue-induced mutagenesis¹⁴ presumably due to the absence of a mismatch correction system. It was expected, therefore, that MNNG-induced mutagenesis should be higher in the mutL-451 dam-3 strain than in wild-type strains. Table 1 shows that this is not the case. The frequency of spontaneous mutation to rifampicin resistance of GM150 (mutL-451 dam-3) is ~100-200-fold greater than that of wild-type strains as expected. However, the MNNG-induced frequency of mutation to rifampicin resistance is not significantly different between the wildtype strains, AB1157 and GM112, and GM150 (mutL-451 dam-3). GM113 (dam-3) exhibits the smaller but consistent spontaneous mutator phenotype characteristic of dam mutants15 but again is not hypermutable by MNNG. It appears, therefore, that while the relative sensitivity to MNNG and DMS of GM113 (dam-3), GM150 (mutL-451 dam-3) and the parental GM112 (dam+) suggests that mismatch correction does occur in wild-type E. coli at m6G-containing base pairs, this correction system does not reduce miscoding mutagenesis due to this lesion. This interpretation is supported by the data of Sklar and Strauss¹⁶ which indicate that E. coli uvrE mutants, which are also deficient in mismatch correction, are normally mutable by MNNG.

Table 1 MNNG-induced mutation to rifampicin resistance

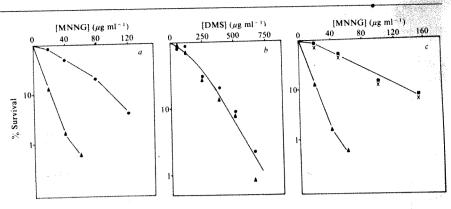

Mut (Rif ^r muta	ation frequents per 10 ⁸	ency bacteria)	
$[MNNG] (\mu g m l^{-1})$	0	5	10	20
Strain				
AB1157 (wild type)	2.6	2,900	4,900	33,000
GM112 (dam ⁺)	1.3	1,100	6,700	25,000
GM113 (dam-3)	94	1,100	3,900	9,600
GM150 (mutL dam-3)	270	2,000	6,200	23,000

Cultures (1 ml) containing $\sim 10^8$ cells ml $^{-1}$ in supplemented minimal medium were treated with MNNG at the concentrations shown at 37 °C for 5 min. After treatment, cells were collected, washed and resuspended at 107 cells ml-1 in supplemented minimal medium and grown at 37 °C for 16-20 h. Appropriate dilutions were plated onto nutrient agar containing rifampicin (100 µg ml⁻¹). Total viable bacteria were determined by plating onto nutrient agar plates. The mutation frequency is expressed as Rif colonies per 10⁸ viable cells.

Sensitivity of dam-3 strains to alkylating agents. Cultures in the exponential growth stage in minimal salts medium supplemented with 0.5% glucose, 0.1% casamino acids and 0.00003% thiamine were exposed to alkylating agent at the concentrations shown at 37 °C for 5 min. After dilution in 10 mM K phosphate pH 7.0, cells were plated onto nutrient agar. Survival was determined after growth at 37 °C for 24 h. a, MNNG sensitivity of lacktriangle, GM112 (dam^+) and lacktriangle, GM113 (dam-3). b, DMS sensitivity of lacktriangle, GM112 (dam^+) and lacktriangle, GM113 (dam-3). c, MNNG sensitivity of ... GM150 (mutL-451 dam-3); x, GM169 (mutS-453 dam-3); and ▲, GM113 (dam-3).

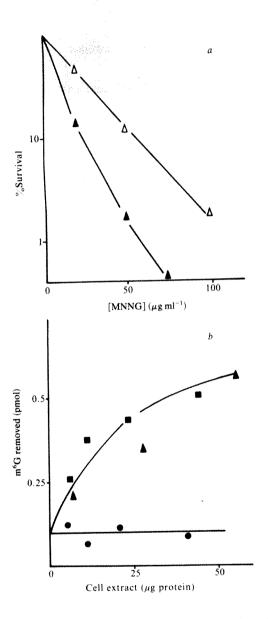

Fig. 2 Effect of adaptation on dam strains. a, MNNG sensitivity. Unadapted cultures (A) were grown and treated as described in Fig. 1 legend. Adapted cultures (\triangle) were grown in medium containing 0.1 µg ml⁻¹ MNNG for 3 h followed by 1 µg ml⁻¹ MNNG for 1 h immediately before treatment. b, Induction of m⁶G methyltransferase activity in adapted dam-3 strains. Adapted and unadapted cultures were grown as described above and then cells were collected, washed and disrupted by sonication. The demethylation of ³H-labelled m⁶G in DNA treated with ³Hmethylnitrosourea was assayed using these crude cell extracts as described elsewhere⁷ ●, GM113 (dam-3) unadapted; ▲, GM113 (dam-3) adapted; , GM1150 (mutL dam-3) adapted

The ineffectiveness of the mismatch correction system in reducing MNNG-induced mutagenesis at m6G may be explained by the presence of the miscoding lesion in the parental DNA strand and by the ambiguous nature of m⁶G coding. After incorporation of 2-aminopurine or bromouracil, the 'incorrect' base remains in the daughter strand. In wild-type cells, the mismatch correction system will recognize the parental strand by its methylation pattern, and will thus always correct the mispair in the correct orientation. However, replication at m6G will direct the incorporation of T or C into daughter DNA. We propose that neither m⁶G:C nor m⁶G:T is a sufficiently good base pair to avoid subsequent recognition by the mismatch correction system. In normal conditions, the mismatch correction system will operate by removing the incorporated T or C, thus allowing a second attempt at the incorporation of the correct base. This second attempt will again result in an imperfect match as no 'correct' base exists. This removal/insertion cycle will presumably continue without check until the dam gene-encoded DNA methylase methylates the GATC sequences in daughter DNA thus removing the strand discrimination necessary for mismatch correction. If the incorporation of C or T opposite m⁶G occurs in approximately the same ratio for the polymerase system involved in replication and in mismatch correction, no net decrease in misincorporation and thus no decrease in mutagenesis will result from the operation of mismatch correction at m6G-containing base pairs.

There are, however, circumstances in which operation of mismatch correction at base pairs containing m6G should be effective in avoiding mutation. If the m6G methyltransferase operates during base removal and replacement and before the action of the dam encoded DNA methylase, the resulting G C or G·T base pair will be either recognizably correct or a true mismatch and dealt with accordingly. In this case, the adaptive response, in addition to its role in removing m⁶G residues before DNA replication, may interact with the mismatch correction system to further reduce mutation frequency.

We thank Dr Michael Green for stimulating discussion throughout this work, and Professor B. A. Bridges and Dr A. R. Lehmann for critical reading of the manuscript. M.G.M. was the recipient of a Faculty Research Award (FRA-149) from the American Cancer Society.

MATTERS ARISING

Early hominids and fire at Chesowanja, Kenya

IN addition to providing valuable new information on the important palaeo-anthropological evidence from Chesowanja, Gowlett $et~al.^1$ state that "burnt clay found at one artefact locality dated to greater than 1.42 ± 0.07 Myr is the earliest known evidence of fire associated with a hominid occupation site" and that "the new find, along with the more tentative evidence from other sites, greatly strengthens the hypothesis that by 1.4 Myr hominids were using and controlling fire".

There are various reasons why the evidence reported should be treated as a good deal less definite than the article implies

Traces of bush fires of presumably natural origin are not uncommon in early and middle Pleistocene deposits of the East African Rift Valley. For example, the fluviatile facies of the Upper Member at Koobi Fora contains numerous reddened, hardened patches that are closely analogous to places where smouldering logs and stumps from modern bush fires have burned down against or into contemporary soils. I have seen and photographed several recent examples of burned patches in East Africa, and at least one rather analogous set of circumstances has been reported in Australia². Where these reddened patches, ancient or modern, erode, a scattering of hard red fragments results. Clasts of this natural 'terracotta' can commonly be observed in the grits and gravels formed on ancient land surfaces. I have frequently observed these clasts in excavations both at Koobi Fora and at Olorgesailie and imagine them to be a widespread phenomenon.

This means that before a new record for a high antiquity of human control over fire can fairly be claimed, there must exist some objective means of distinguishing a hearth controlled by hominids from the baking effects of a bush fire. Gowlett et al. seem to claim that this distinction is made possible by the contrast between a determination of a 400 °C baking temperature for the burned material from site GnJi 1/6E compared with over 600 °C for "baking around a recently burned tree stump". I am sceptical that a difference between two isolated determinations can be relied on as a general criterion, and I would predict that if a series of bushfire baked samples is measured, the range of temperatures will be found to overlap with campfire temperatures.

The most convincing evidence for human control over fire in an open site would come from evidence of a localized, burned patch that was not a burned stump, inside the confines of artefactual refuse which had not been unduly disturbed by fluvial transport³. However, paragraph 4 and Fig. 2 of the article¹ make it clear that all the finds, including the burned earth fragments, were recovered from material that was swept together in the bed of a small channel. The finds can thus be regarded as provocative and suggestive, but no more.

The question of the antiquity of human control over fire is of more than curiosity value in our understanding of prehistory and human evolution. Besides the indication provided of an advance in mental capacity, fire may well have had important effects on feeding strategies and diet breadth. Control over fire also would have allowed humans to raise the frequency of bush fires and thereby to have a marked effect on vegetation patterns.

The article by Gowlett et al., and others that they cite, serve the useful purpose of emphasizing that we still do not know whether humans controlled fire before ~0.5 Myr and if so, how long before. I suspect that development of suitable discriminants between traces of bush fires and controlled fire will require collaboration of physicists and archaeologists in the field during excavations.

GOWLETT, HARRIS AND WOOD REPLY—Isaac provides us with an opportunity to explain further why we consider that the context of the burnt clay at site GnJi 1/6E deserves serious consideration as evidence linking fire with hominid activity.

Isaac describes a series of circumstances which would provide the least ambiguous evidence of controlled fire on a single open site, and few would dispute his general criteria. We agree, too, that circumstances where baking is not proved, or where evidence of hominid activity is tenuous, provide inadequate testimony. Where we clearly disagree with Isaac is over the idea that a site with much stronger evidence should have no effect on what can be admitted as a working hypothesis.

We emphasize again that the evidence of fire at Chesowanja is quite definite: the clay was burned, and its association with the artefacts is direct and physical. Isaac rightly points out that the apparently low baking temperature of the clay is inconclusive evidence of the nature of the fire. This we clearly acknowledged, and it is why we advocated studies of the cooling

rate of the clay. We share with Isaac the hope that future investigations of experimental fires will assist in the interpretation of such data.

Strength of association is an important point. Given the controversy surrounding the contexts of all early sites1, Isaac legitimately raises the possibility that the baked clay and artefacts may have been swept together. The evidence does not, however, support this view. On the contrary, we have good reason to believe that a reverse process has operated, and that the clay lumps, starting together, have crept apart. The presence of several large lumps together (square 82-83 E/111-112 S), including three weighing 262, 217 and 175 g respectively and which retain sharp edges and protuberances, argues very strongly against any significant water transport, as indeed does the whole context of fine-grained sediments. These finds occur close to a modern erosion gully, which prevents further exploration to the north and west, so that the scatter of smaller clay lumps to the opposite corner of the excavation is actually a vital bonus to interpretation, as it rules out any possibility of the burnt material deriving from recent superficial disturbance.

We welcome Isaac's contribution, for it is important that the cases for and against early human control of fire, at Chesowanja or elsewhere, should be fully aired. We also agree that progress in this field of research will be much facilitated by closer practical collaboration between physicists and archaeologists. Nonetheless, we stand firmly by the view that the Chesowanja evidence at strengthens the hypothesis that fire was associated with hominid activities more than 1 Myr ago. We shall present additional evidence in due course.

We hope that this exchange will help to stimulate research on a wider scale, for although the evolutionary importance of controlled fire has been appreciated for over a century², new technical means for exploring its history now provide increasingly better chances of adding to the facts.

BOOK REVIEWS

Rolled over by technology?

Bruce Williams

THE God that limped? Hephaestus, the Greek god of fire and metalworking, was eagerly sought after for his technological skills. But he was ugly, irascible, often disliked by the other gods, and he had a pronounced limp. For Colin Norman this makes Hephaestus the appropriate symbol for modern technology — powerful and versatile but often marred by crippling defects.

A.N. Whitehead once wrote that the greatest invention of the nineteenth century was the invention of the art of invention. During the Second World War, J.A. Schumpeter predicted that industrial innovation would become a routine function of organized R & D. Planned inventions of weapons during the War, and a great range of planned inventions after it - sputnik, rockets to put men on the Moon and bring them back again, computers, chips, a great range of pesticides and ethical drugs, high-yield grains to create the green revolution encouraged many to believe that the twentieth century had invented the science of invention. But that euphoria was undermined by the extent of serious problems created or intensified by the massive increases in R & D activities (the unforeseen side effects of new drugs, radioactive wastes, the displacement of labour), by fears that some of the solutions are clever but ephemeral (boosting crop yields from oil-based fertilizers), and by growing doubts about the capacity of R & D to contribute much to urban decay, poverty in the Third World, de-skilling, technological unemployment and the exhaustion of non-renewable resources.

While recognizing the immense social, economic and cultural benefits that science and technology have brought to society, Norman concentrates more on the social and environmental costs in the global economy. This is because he judged that present policies and trends are dangerous - the great post-War boom was built on an unstable foundation of cheap oil, and even now R & D in North America is more suited to the military needs of the 1950s than to the social needs of the 1980s. Whether the mismatch between defence and social needs in R & D objectives is any greater now than in the 1950s is not explored but is implied in his comments on the energy crisis and the problems of producing sufficient food, shelter and material resources for a population that will swell to six billion by the year 2000.

For those directly involved, there has

The God That Limps: Science and Technology in the Eighties. By Colin Norman. Pp.224. ISBN 0-393-01504-1. (W.W. Norton: 1982.) £10.50, \$18.25.

always been an element of fear associated with the introduction of new technologies. Norman refers to the growth of a more general fear that social changes are determined by technological change that is driven chiefly by its own momentum -"we even speak of new generations of computers, automobiles and other high technology goods as if they were biological descendants of earlier models". He explains these growing fears in terms of the complexity of many modern technologies and the centralization of decision-making by both Governments and large corporations. On "the fear that society is simply a product of its technology", he points to the major part that Governments play in determining the extent and directions of R & D and the numbers of scientists and engineers, and to the vast amount of innovation in, for example, weapons, space vehicles, law enforcement technologies, health care systems, as well as to the research activities in astronomy, high-energy physics and molecular biology, that cannot be explained even in terms of economic forces. Technological, economic and political forces interact to produce a complex array of pressures that push and pull technological developments along certain paths. The technical imperatives only define what is possible.

How, then, may technological development be pushed and pulled on to the path leading to a humane and sustainable society? He suggests four things - first, a better balance between unfettered market forces and Government constraints on market forces to reduce social costs; second, a broader public participation in the decisions that lead to the generation and adoption of new technology to give those most likely to be affected a role in its planning and to reduce some of the negative impacts; third, a greater access to modern technology in developing countries, and on more favourable terms, and an increase in their capacity to generate and apply technologies most suited to their own needs and resources; and fourth, a recognition that technology cannot by itself solve social and political problems.

His first suggestion is based on the judgement that the unfettered workings of the market system are enormously powerful in stimulating the development

and application of some technologies but cannot always be relied on to steer technological developments along socially appropriate paths. There is therefore a need for Governments to establish certain constraints - on pollution and working conditions - and to supplement market forces by subsidies for the production of certain commodities or services (including R & D). Government constraints on and supplements to market forces have been established for many years, the fact that competition is a form of social control based on legislation has been firmly accepted, and the theory of how to use taxes and bounties to control market forces when private and public costs or benefits diverge was established by Pigou 50 years ago. That Governments have not taken the appropriate actions - and Norman recognizes that some of their regulatory actions (on, for example, oil and gas prices in the USA) have made things worse - is sometimes due to the power of special interests, sometimes to unwisdom, and sometimes to the inability of scientists or engineers to provide firm evidence on the costs and benefits of various proposals for regulatory action. Norman writes of the urgent need for regulatory reform but his account of just what should be done and how is too cursory.

Norman admits that the experience of public participation in decision-making on new technologies is limited, but he is optimistic that it would have a beneficial effect on technological development and reduce some of the negative impacts.

He gives some examples of effective public participation in decisions in the USA, for example the Alaska Pipeline and the SST, and it is reasonable to demand and expect improved environmental impact statements and public discussions of them. But he underestimates the problems of participation. With new printing methods, for example, at what stages in the development of several technologies could there have been "public participation"? And when the publishers decide to use the labour-saving new technology who is to be "the public" to participate in the decisions? The new technologies that affect an industry may be developed and established outside that industry or in another country. The "compulsions of competition" are very complex, the effects are frequently impossible to foresee and there is need for much more consideration of how to distribute the costs of technical change.

His suggestions for providing the Third World with technology on better terms, for cooperation with the developing countries in the transfer and adaptation of technologies, and for the indigenous development of appropriate technologies are more positive and complete.

The God That Limps is a timely and stimulating book. In warning of the need to recognize that technology cannot of itself

solve social and political problems Colin Norman allows a much greater role for technology than Jay Forrester, who recently asked whether for the past 200 years technology has done much more than cope with the consequences of population growth.

Sir Bruce Williams is Director of The Technical Change Centre, London, and Visiting Professor at Imperial College, University of London.

Meteorology enters the mesoscale era

Edward J.Zipser

Meso-scale Atmospheric Circulations. By B. W. Atkinson. Pp.495. ISBN 0-12-065960-3. (Academic: 1981.) £32.40, \$78.

FIFTY years hence, it may be difficult to explain to students how most meteorologists contrived to postpone to the 1980s their discovery of the importance of the mesoscale, the intermediate scales of motion. Indeed, how could so many observers of the natural world have accepted for so long that local weather events were controlled by large-scale systems with a spectral gap in the mesoscale (tens to hundreds of kilometres)? While better observations and numerical models have improved forecasts on time scales of 1-3 days, our ability to forecast 1-12 hours into the future, or to anticipate severe weather or flooding rains, has stagnated for 20 years.

Atkinson has written the first book in mesoscale meteorology, and his pioneering effort sets a high standard. He has made eminently reasonable selections of what to include and what to exclude. Each subject is treated in a similar manner, with observational knowledge summarized first, followed by theories, numerical simulation results and, where applicable, hardware models.

Many of the subjects have never been summarized comprehensively before. The first half of the book is a superb, systematic review of topographically induced flows, including lee waves, downslope winds, sea-and land-breeze circulations, and slope and valley wind circulations. The literature has been surveyed exhaustively; numerous papers hitherto unknown to this reviewer are placed in context and, where appropriate, recent papers highlighted. It will be difficult to improve upon this treatment, and Atkinson's book could well become the classic reference work on these subjects for the next 20 years.

Severe local storms have been the centrepiece of mesoscale meteorology for many years. Storms which generate hail, tornadoes and other damaging winds are challenging subjects because they are intrinsically scale-interaction phenomena. The severe storms chapter is excellent on convective storms in general, and in

summarizing recent literature on hailstorms, but it is rather weak on the rotational aspects and on recent literature on tornadic storms. The recent work on squall lines is well-covered, but it should have been clearly separated from the severe storms chapter and placed in a section on mesoscale convective systems, which are larger than individual storms. By not distinguishing between organized convection and severe convection, as where squall lines are claimed to be severe by definition, Atkinson's book will help some long-held misconceptions to persist for a few more years.

After a useful chapter largely concerned with recent results on shallow cellular circulations, the book closes by treating mesoscale circulations within cyclones. Atkinson himself has made contributions to extratropical cyclone studies, and this section is strong. Because this type of research concentrates upon radar description of precipitation distribution, however, it may not be obvious to all readers when it is proper to make inferences about mesoscale wind circulations in the absence of direct measurements. In addition, the section on tropical cyclones, like the literature on which it is based, is somewhat uneven. The recent improvement in aircraft instrumentation should lead to the need to undate this section in the near future. For unknown reasons, no mention is made of cyclonic circulations in the tropics other than tropical storms.

This book does not attempt to be all things to all people; it deals with basic science, not applied science. The sea breeze, for example, is treated as a basic fluid flow, and the importance of that flow for precipitation distribution and air quality, although mentioned, is covered either briefly or not at all.

The author can take pride in fulfilling a long-standing need for a text in mesoscale meteorology, which is sure to stand as a basic reference work for decades. Nearly all meteorologists will want a copy close at hand.

Edward J. Zipser is a Senior Scientist in the Convective Storms Division at the National Center for Atmospheric Research, Boulder, Colorado. (NCAR is sponsored by the National Science Foundation.)

People and change

William Brass

Population and Technology. By Ester Boserup. Pp.225. UK ISBN 0-631-12817-4 (Basil Blackwell: 1981); US ISBN 0-226-06673-8 (University of Chicago Press: 1981.) £12.50, \$17.50.

In the early 1960s Ester Boserup began to propagate the view that population growth was one of the fundamental causes of the development of new agricultural methods. The importance of her work was less in the idea than in the lucidity and coherence of the demonstration. The present book is a wider essay on a similar theme, the interaction of population growth and technological change.

The central idea is that population factors have been a major determinant of the introduction of (or failure to exploit) new methods for the organization and improvement of production. Since the scope of the book is the whole of human history, much of it is logically concerned with agricultural output. The presentation is not of a highly structured argument from the idea to the consequences; rather there is an extensive historical review beginning with the transition from hunting-gathering to agriculture, and ending with the population-technological relationships in the less-developed countries of the present day. In between there are accounts of the establishment of urban civilizations, with particularly interesting sections on Mesopotamia, the Maya and China, the development of trade and industry in Europe, mass-migration to the United States and elsewhere, the transfer of industrial technologies to Asia and much else. Despite the unifying theme there is no dogmatism; population growth may be taken as the driving force but the importance of effects in the reverse direction is implicitly accepted.

Again and again in traditional works of pre-history and history there is a sentence which states that as a consequence of technological change (settled agriculture, spread of the use of iron, industrial invention) the population grew. There is seldom even a cursory consideration of how this happened; the way in which the changes could have altered fertility and/or mortality appropriately is left obscure. The large increase in the knowledge of the basic demography of less-developed communities in recent years has intensified the difficulty of the explanation. No simple, universal link between technological development and reduced mortality or increased fertility can be demonstrated.

The God that Limps: Science and Technology in the Eighties, by Colin Norman (reviewed on page 871) will be published in Great Britain on 26 May 1982.

The turn-around in the direction of the pressures, proposed by Ester Boserup, is stimulating and attractive although it leaves the causes of population growth in darkness, almost as a natural law of human history.

In a relatively short book of such a wide scope the evidence to support the thesis is inevitably condensed and the statements sweeping. Readers with a specialist knowledge of particular topics are likely to find assessments which do not take account of the most up-to-date research; the publications relied upon are not always the most reputable. For example, the discussions of the basic demography of the biosocial determinants of fertility and mortality, which are of critical significance for the reversal of the older views on the direction

of the relation between population growth and technological change, are surprisingly weak in depth of knowledge and citations of relevant research. Nevertheless they are sensible and only marginally misleading.

This is an exciting book, full of ideas which are provocative because they are unconventional and yet plausible. One of many possible examples is the examination of the minimum population densities needed for the development of urbanization at the relevant stage of technology. There is undoubtedly much to criticize in detail, but only by studies of this kind can the essential broad syntheses be achieved.

William Brass is Professor of Medical Demography and Director of the Centre for Population Studies at the London School of Hygiene and Tropical Medicine.

The doctor of revolution as letter writer

Gavin Bridson

The Letters of Erasmus Darwin. Edited by Desmond King-Hele. Pp.363. ISBN 0-521-23706-8. (Cambridge University Press: 1981.) £45. \$95.

THAT remarkable polymath, Dr Darwin, has been singularly fortunate in having such a loyal admirer in Desmond King-Hele who has stayed beside his hero for some 20 years. His introduction to Erasmus Darwin (1963), followed by The Essential Writings (1968), Doctor of Revolution (1977), introductions to reprints of Darwin's Botanic Garden and The Temple of Nature (1973), and articles in Nature and elsewhere, all demonstrate this loyalty. His high regard for the amiable, versatile and near perfect eighteenth-century genius is no secret. In Doctor of Revolution he declared

Though I may be biased, I regard Erasmus Darwin as the greatest Englishman of the eighteenth century. If you disagree, can you name anyone else in the past 250 years with a list of accomplishments so numerous, so notable and so varied?

These he summarized in a list of 75 achievements which included such unsuspected topics as abolition of slavery, air travel, biological pest control, copying machines, oil drilling, rocket motors, speaking-machines, submarines, water closets and women's lib. He optimistically added that

The flow of specialised articles in journals has been increasing, and, if the momentum continues, we may yet see Darwin receiving the kind of scholarly attention that has been lavished on lesser figures like Boswell or Horace Walpole.

A glance at the *Isis* bibliographies shows that the flow has not been so great and that King-Hele's writings still provide a major

tributary. Little surprise, then, that he himself should edit Darwin's letters.

After a wide search for manuscripts in Britain and the United States, King-Hele believes that he has located the great majority of surviving letters and that this 'provides a balanced and reasonably complete picture of Darwin the letterwriter in all his moods". For a man whose published writings ran to a million and a half words it is disappointing to find that the picture is composed of only 272 examples written between 1749 and 1802. No guess is made as to the likely quantity that may once have existed. We find that Boulton, Watt and Wedgwood kept 103 letters between them, and his grandson, Charles, quoted from 30 out of a collection that has not survived in manuscript. We must be grateful that as many as 88 other recipients make up the rest, that they spread over all but a handful of Darwin's. 50 or so adult years, and that they reflect so much of the man and his achievements for about half of King-Hele's list of 75 are apparently touched upon here. 187 letters survive in manuscript (162 in Darwin's own hand) and the rest are taken from published sources.

King-Hele has developed a meticulous editorial apparatus for the treatment of the chronologically presented sequence. Each letter is printed without the inclusion of any editorial distractions, according to his stated rules for transcription. Passages of some length are omitted in a few instances where these amount to an inserted "paper", such as details of Darwin's polygraphic machine and instructions on landscape drawing which have been removed from two 1779 letters. However, it is particularly pleasing to have facsimiles of the numerous sketches by means of which Darwin illuminated his observations, ideas and inventions.

The editor's notes fill the spaces between the letters, and fill they sometimes do - 18 separate notes on a letter to Watt, and 100 lines of small-type notes on a 12-line letter to Joseph Banks. With a modest number to work on. King-Hele has been able to examine each letter under a powerful lens and reveal minutiae that might escape even the attentive reader's eye. Twenty years' research have brought him to an intimacy with his subject that could scarcely be equalled on the basis of surviving records, contemporary comment and astute interpretation. A dazzling breadth of erudition is woven into the fabric of his scores of enthusiastic and revealing notes. No stone, it seems, remains unturned and one admires his ability to meet the demands that the wealth of Darwin's ideas and activities has placed on him.

Precise information on the source, previous printings and text used for transcription, accompanies each letter, together with notes on the recipient, the date of the letter, explanations of obscurities and identification of people, places and things. A handbook on Darwin's life and times could be assembled from such detailed, well informed and bibliographically replete commentaries. Their biographical content alone is remarkable, for which the assistance of Hugh Torrens is acknowledged.

Fortunately for the reader, studiously careful guidance to all this scholarship is provided by means of name and subject indexes, a chronology, list of recipients and a gallery of 48 portraits, all the product of much thought and time. In fact the body of the text is so replete with editorial matter that it makes for slow reading if one progresses through letters and notes in turn.

As we have come to know from many previously published extracts, Darwin's letters are extremely engaging and entertaining reading, vividly reflecting his moods, interests, personal relations and doings. One really must read through runs of letters by themselves to get their flavour and then retrace one's steps for the additional pleasure of King-Hele's commentaries. Some of the letters are frankly dull, dealing with pedestrian business matters, and but for the overall scarcity of his correspondence might not have been included or accorded such reverential treatment. But most are packed with interest, varying from light-hearted banter to grave formality, and including verse, poignantly expressed sentiments, highly detailed technical descriptions. comments of immense foresight and wisdom, and reflections of his endless vigour, excitement with life and overwhelming good nature — in short, all that his biographers have taught us to expect.

Gavin Bridson is Librarian and Archivist to the Linnean Society of London, and joint compiler of Natural History Manuscript Resources in the British Isles (Mansell, 1980).

The what, why and wherefore of cells

R.E. Stephens

Ultrastructure, Macromolecules, and Evolution. By Lawrence S. Dillon. Pp. 708. ISBN 0-306-40528-8. (Plenum: 1981.) £43.79, \$69.50.

IN THIS second part of an intended trilogy, Lawrence Dillon interweaves discussion of evolutionary and cell structural relationships in order to consider genetic mechanisms working at the cellular level and to reconsider phylogeny from a cellular viewpoint. This is a formidable task because of the breadth and depth of information which must be assembled, assimilated and analysed. In terms of defining general principles, Dillon succeeds admirably; in terms of accurately documenting his background data, he fails in certain areas. Most of these failures are inconsequential to the ultimate conclusions, but they are disconcerting nevertheless.

The author has arranged his material into four areas of comparative cytology: cell motility, secretory organelles, energyprocessing organelles, and karyo- and cytokinesis. He begins with a detailed account of the structural chemistry of membranes in general, giving an excellent historical perspective. Oddly, he follows this with four somewhat uneven chapters on cell motility before returning again to membrane-based systems. Motility is covered in chapters on microtubules and microfilaments, cytoplasmic movement, the flagellum and the basal apparatus. There are some serious problems in this area, to which I will return below.

Secretory systems are dealt with in two chapters — the endoplasmic reticulum and the Golgi apparatus are treated as a continuum, the "endomembrane system", while the lysosome, peroxisome and related structures are dealt with as the "vesicular system". This manner of presentation is quite informative in a comparative sense and it is logically and clearly arranged.

Three closely-correlated chapters are devoted to "energy-oriented organelles". The first discusses general aspects of cell respiration and includes a lucid consideration of the evolution of the tricarboxylic acid cycle; the remaining two cover mitochondria and chloroplasts, their comparative structure, replication and development in numerous organisms. Here, Dillon presents a well-balanced account of the two contending theories for the phylogenetic origin of these organelles: the endosymbiotic concept and the episome theory. He clearly favours the latter and presents additional evidence for it, based mainly upon some compelling evolutionary considerations.

Dillon ends this work with a comparison of both nuclear and cytoplasmic division

mechanisms in a multitude of organisms. Here, considering the abundance of information now available, I would have liked to see further examples, mention of odd exceptions and more detail, but the coverage is certainly adequate for the author's purposes. Tacked on to this final chapter are Dillon's two principal conclusions, concerning the inadequacy of simple mechanistic theory (i.e. the central dogma and self-assembly) to account for the development of cell structures and his well-stated contention that the phylogenetic stages of evolution, examined in terms of cellular evolution, allow no clear division between plants and animals. protozoans and algae, or even prokaryotes and eukaryotes. Certainly not everyone will agree with his views, but he raises many points that cannot be ignored.

The problems in the motility chapters. mentioned previously, range from simple inaccuracy (outer doublet B-subfibres contain 10 or 11 protofilaments, not 9; p.73 and p.143) and typographic atrocities (actinomysin for actinomycin, p.255; actinomyosin for actomyosin, p.407), to gross errors in reporting published conclusions (no analysis of doublet A and B tubulin components ever showed a specific number of residue differences, p.174) and unwarranted generalizations (in only one species has the ciliary membrane been shown to differ from the flagellar membrane, p. 163). Also there are mistakes and misjudgements in citation priority, attributing the right facts to the wrong workers, and making overly broad generalizations from authors' more conservative conclusions. These, however, are no more than minor flaws which may easily be corrected in a second edition.

Perhaps more seriously, the dust jacket promises a new concept of flagellar movement. Dr Dillon argues against the widely-accepted sliding filament theory. concluding that it simply isn't so because microtubules are attached to the basal body. He begins his arguments by not mentioning Peter Satir's classic work on the subject, and by not considering that sliding is local and constrained and that the axoneme may twist in response to sliding. He concludes that the tubules themselves must change length, ignoring the work of D. P. Costello who argued all of this a decade ago and did so far more convincingly. The book would be much better off without this "new concept", particularly since it has nothing to do with Dillon's major premise.

Chemical differences in tubulins are central to Dillon's prime example for the workings of the cellular genetic mechanism (pp.174-176; p.558). With a simple self-assembly mechanism, how do the tubulins of the outer doublets and central pair sort

themselves out from each other and from cytoplasmic tubulin and, furthermore, when assembled into a 9 + 2 structure, how are dynein, nexin and spoke sites specified? The author contends that the mechanisms must be enzymatic. If the tubulins are really as different as Dillon implies, they should be able to sort themselves out easily (specific recognition sites) and also to specify binding sites when assembled (differences in surface lattice). In reality, however, the tubulins are not very different and some observed differences are probably due to post-translational modification, perhaps even after assembly. The truth of the mechanisms probably lies somewhere between these two viewpoints. This potentially important example sorely lacks authority and is likely to mislead the casual reader.

As an evolutionary exposition, Ultrastructure, Macromolecules, and Evolution is unique; nowhere is such a broad sweep presented so succinctly in a single source. The references, cited with full title and grouped by chapter at the end of the book, are quite valuable in their own right. This will be a useful reference book for those interested in comparative ultrastructure and certain phylogenetic aspects of biochemistry, and could also serve as a text for a graduate-level cell structure—function—evolution course, leading students easily back to the original source material.

R.E. Stephens is Resident Investigator at the Marine Biological Laboratory, Woods Hole, Massachusetts, and Adjunct Professor of Physiology at the Boston University School of Medicine.

The healing way

N.R. Rowell

Tissue Repair and Regeneration. Handbook of Inflammation, Vol.3. Edited by L.E. Glynn. Pp.579. ISBN 0-444-80278-9. (Elsevier/North-Holland Biomedical: 1981.) \$136.50, Dfl.280.

REPAIR is essential to life, but what governs whether the body replaces damaged or dead tissue by tissue indistinguishable from the original, by scar or by a mixture of both, is a mystery. A distinguished international group of contributors here present a series of reviews concerning certain aspects of this problem. It is the third of five volumes dealing with inflammation, the first two of which dealt with chemical messengers and cell biology.

In the opening chapter Gabbiana and Rungger-Brändle discuss the fibroblast, the fundamental cell in repair. From work in human beings and experimental animals, this cell has been shown to be remarkably adaptable and may after its morphological, biochemical functional features. In wound healing, fibroblasts, and possibly other cells, transform into contractile cells called myelofibroblasts and these are probably concerned in wound contraction. Unfortunately, the authors cannot yet identify the factors controlling this process. Fibroblasts are also involved in the synthesis and metabolism of connective tissue, including collagen. Collagen has several functions as well as its primary role as a support. Duance and Bailey describe the five known types of collagen but admit that the relationship between structure and function is unknown. As many as 15 cell types may be involved in wound healing, including cells derived from the bone marrow, thymus, reticuloendothelial system and liver, as well as the cells of the tissues involved.

In regeneration, growth-regulating factors encourage the tissue to replace damaged areas with normal-functioning cells. Usually the formation of scar tissue is preceded by physical or other trauma, but this is not always the case; for example, in Dupuytren's contracture and scleroderma trauma is absent.

The book is nicely balanced between a consideration of basic processes and how these apply in the skin, central nervous system, lungs, heart and kidney. The editor himself has written an excellent chapter on the pathology of scar tissue, which links several of the authors' contributions. All authors agree that hyperplasia and atrophy, regeneration and repair are extremely complex phenomena, but in this book they have generally succeeded in making the subject intelligible to their readers.

Each chapter includes between 200 and 500 references which indicates the coverage of the subject. It also probably accounts for the fact that there are few references after 1978, although in one chapter additional notes have been added in 1980.

I can recommend this excellent book; it will be very useful for medical and non-medical scientists in many disciplines. Considering the complexity of the subject, the book is easy to read — presumably the result of sound editing — and there are few mistakes of any note and little overlap between contributions. Further volumes on the immunology of inflammation and the molecular basis for anti-inflammatory therapy will round off the series, which, when complete, should prove a most valuable addition to medical libraries in particular.

N.R. Rowell is Reader in Dermatology at the University of Leeds, and Senior Consultant Physician in the Department of Dermatology, Leeds General Infirmary.

Modelling the growth of literature

B.C. Vickery

Scientific Information Systems and the Principle of Selectivity. By W. Goffman and K.S. Warren. Pp.191. ISBN 0-03-056081-0. (Praeger/Holt-Saunders: 1980.) £13.75, \$19.95.

IMPRESSED by the ever-growing rate of scientific publication, the authors of this book decided that the process of scientific communication needed to be studied as an "ecosystem". They develop mathematical model for the growth of the literature in a defined subject, and then go on to a detailed quantitative analysis of various bodies of literature. The main experimental data consist of a bibliography of schistosomiasis, covering the period 1852-1962 and comprising over 10,000 references. There is little use made of the mathematical model in subsequent analysis, and there is no convincing demonstration of its validity.

Six kinds of analysis were made: distribution of articles and authors by language and by date; multiple publication by individual authors; multiple authorship of articles; most prolific journal titles and distribution of articles among journals; similar analyses for sub-areas of schistosomiasis research; and movement of researchers among sub-areas. The most interesting of the analyses is that based on co-authorship of articles. If authors A and B collaborate, also B and C, as well as C and D, then A,B,C,D can be said to form a network. Of the 6,500 authors in the schistosomiasis bibliography, 2,300 had no collaborators, but there was one big network that embraced 1,750 authors, as well as several hundred smaller networks.

This network of co-authorship is the only real evidence of scientific communication that is examined in the book. The citation of one author by another (implying awareness and probable reading of another's work) is not explored, still less any other forms of communication (attendance at conferences, for example).

The authors then conducted a qualitative evaluation of the schistosomiasis literature. Some 47 active workers in this subject were chosen with the aid of expert advisers. Each was asked to examine the bibliography and indicate "articles you deem of lasting importance". Over 3,000 of the 10,000 articles were selected at least once; about 1,600 at least twice; 471 at least five times; and 69 papers were selected 12 times or more. As one moved from the 3,000 to the 69, the likelihood of the authors being members of the large coauthorship network not surprisingly increased from 40 per cent to 70 per cent.

Goffman and Warren are convinced that "quality filtering" of scientific literature is needed in order to ease the task of retrieval, and offer proposals based on citation in review papers as an indicator of quality. I

find it doubtful whether any further mechanism — other than the review papers themselves — is needed by the scientific community.

The book presents a number of interesting ideas about the structure of scientific literature, and Goffman and Warren certainly extract as much as they can from the data used. But this information simply consists of the authors, title and source of each article, plus its evaluation by experts. There is no indication of what the authors have read, or who reads their contribution. In order to get a more rounded understanding of scientific communication, the book needs to be complemented by the reading of work such as that of Garvey, who has taken these other factors into consideration.

Brian Vickery is Director of the School of Library Archive and Information Studies, University College London.

The complete angler

Bruce R. Moore

Circular Statistics in Biology. By Edward Batschelet. Pp.372. ISBN 0-12-081050-6. (Academic: 1981.) £28.80, \$69.50.

MANY scientists who rarely otherwise cite secondary sources, do so routinely when referring to statistical tests. Several reasons for this tradition are evident, not the least of which is that original statistics papers are meant to be read by statisticians.

This use of secondary sources is frequently quite harmless, since clear and accurate statistics texts are available at many levels. It has sometimes been less satisfactory, however, for that substantial minority of scientists whose data occur in vector form. The *t*-tests and ANOVAs of everyday statistics are seldom applicable to angular data. A number of special tests have, in fact, been developed, but they are not described in most statistics texts and are therefore missed by many potential users. In consequence, statistical inference based upon mere intuition has become the norm in certain areas.

Against this background, one finds isolated regions where the special tests have been thoroughly exploited. The source most often cited in these areas is an out-of-print monograph by Edward Batschelet (American Institute of Biological Sciences, 1965). Although extremely specialized, this work has become for many readers not only a highly trusted source but even an object of personal affection. Such persons were pleased to learn in recent years that, while approaching retirement, Professor

Batschelet was preparing a book-length expansion of the monograph.

Although he died unexpectedly a few months after retirement, Professor Batschelet's manuscript had been completed, and the book has now been published. Readers will find in it the same clarity of style and careful choice of example which characterized the earlier monograph. Essentially, Batschelet describes some 30 tests for vector clustering, group differences, correlations and goodness-of-fit. Most of these are briefly explained, then illustrated with one or more examples. Few derivations are given. The examples are taken almost entirely from biology, but readers from other disciplines should find them clear and easily translatable. Only slightly less clear are the supporting chapters describing various circular distributions and simple mathematical techniques.

There are a few mistakes: Example 6.5.1 requires k = 80; 7.4.1, $a_s = 2.25$; 7.7.1, $T^2 = 154$; p.183, Σ sines = -1.48; and Table 9.3.2, a fresh beginning. The two-stage application of Mardia and Watson-

Wheeler tests in 7.8 is appropriate, but the sanctioned alternative combination of Mardia and Watson-Williams is not. The choice of median peak hour in 1.5.2 is not altogether proper, nor is the "careful" breaking of ties recommended in 9.3. But a few such lapses are almost inevitable; while unfortunate, they detract very little from the value of the book.

Circular Statistics should prove extremely helpful to almost anyone with vector data. It can be recommended also to potential writers of more general statistics texts. A worthwhile precedent is being set here by J. Zar's Biostatistical Analysis, the second edition of which, shortly to be published by Prentice Hall, includes two full chapters on vector-statistical methods. Batschelet offers an excellent starting point for a generation of other such chapters.

Altogether, we have received a most valuable legacy in this long-awaited and authoritative work.

Bruce Moore is in the Department of Psychology at Dalhousie University, Halifax, Nova Scotia.

Life viewed in the particular

B. C. Goodwin

The Foundations of Biological Theory. By E. H. Mercer. Pp.242. ISBN 0-471-08797-1 (Wiley: 1981.) £29.20, \$22.55.

A PERENNIAL source of tension in science arises from the possibility of explaining phenomena in two distinct ways: either as a result of law, whereby they become intelligible in terms of principles at once simpler and more general than the phenomena themselves; or as a result of contingencies, of events that just happened to occur. A classic example of the latter was Buffon's suggestion that our planetary system arose from a chance event, a nearcollision of the primitive Sun with another celestial body. Kant, on the other hand, suggested that orbiting planets arise by necessity (i.e. law) from gravitational instabilities in rotating masses of gas. Buffon the biologist chose a description in terms of particulars; Kant the philosopher sought a decription in terms of universals. Current theory favours Kant, with farreaching consequences, among them the expected existence of countless other planetary systems in the cosmos with conditions allowing life to evolve.

Biologists still favour description in terms of particulars, and this view dominates E. H. Mercer's clearly-written book on the conceptual foundations of biological theory. He assumes that all biological phenomena are instances of physical and chemical laws, but because of hereditary mechanisms, certain processes that arise by chance in organisms can be perpetuated so that organisms become the sediments of historical contingencies which constrain in adaptively successful ways physical and chemical possibilities. For him "the historical course of events leading up to the present situation . . . provides biology with its theory". The task of theoretical biology is thus to tell the story of evolution, a point of view prevalent since Darwin. This has the important consequence that the biological realm is not rationally intelligible in the sense of revealing the operation of universal principles of organization and transformation. Life on other planets could look very different.

Mercer bases his analysis on the important distinction, established in Newtonian physics, between universal laws embodied in differential equations and the particular conditions which define a unique solution for a specific process. Although "boundary conditions" usually refer to particulars for fields, Mercer uses this term to include initial conditions, and he extends it to the more general concept of constraint, which simply imposes some limitation on the system. His treatment of biological organization is then presented in terms of a hierarchy of constraints which he describes as "organising or operational rules that define functional relationships between the units and regulate their interactions". The goal or purpose of biological organization is, he assumes, to ensure its survival. This is an extrinsic stability criterion.

Many of the arguments are already familiar from the writing of Polanyi, Pattee, Riedl and others, to whom Mercer refers. Relevant ancillary concepts from such areas as information and control theory, thermodynamics and kinetics are clearly described, and these ideas are then used to describe organismic processes in terms of a hierarchy of constraints, with descriptive detail from biochemistry, genetics and development. A more analytical treatment in terms of nonequilibrium thermodynamics is less successful since Mercer claims that the near-equilibrium theory gives satisfactory account of the dynamic stability exhibited by adult organisms". However, such periodicities as circadian rhythms, neural pacemakers and peristaltic rhythms are excluded from this domain. Also, he incorrectly implies that a thermodynamic characterization has been given of these and other far-fromequilibrium phenomena; what has been obtained is useful insights into non-linear behaviour and symmetry-breaking by a number of investigators using stability and bifurcation theory, some of which Mercer describes.

Chance plays the conventional role of generating the variety on which natural selection operates, and the various sources from quantum indeterminacy to macroscopic uncertainty in bifurcations of "chaotic systems" and chromosome crossing-over are described. A final chapter outlining the origin and evolution of animate systems, continuous with physical evolution, completes the work. We are thus provided with a detailed account of organisms as constrained physico-chemical survival machines, both their hierarchical structure and their variety arising by chance.

Mercer's book has the virtues of clarity and extensive scholarship, only occasionally flawed by an incomplete grasp of subject matter. It provides an up-to-date account of neo-Darwinist thinking dominated by the "evolutionary paradigm", which defines the prevalent conceptual tradition in contemporary biology. However, there will continue to be those who, remembering Kant and seeing clear evidence of systematic regularity as well as variety in the biological realm, feel that Darwin's abandonment of explanation by law and his preoccupation with particulars (adaptation and inheritance), though historically understandable, was nevertheless misguided. For them, Mercer's approach will be unsatisfactory, and they will continue to seek a rational foundation for biology whereby organisms and their evolution become intelligible in terms of universal laws of organization and transformation, not simply in terms of chance events and survival.

Brian Goodwin is Reader in Developmental Biology at the University of Sussex.

ANGEL, M. V. and O'BRIEN, J. (eds). Progress in Oceanography, Vol. 9

Pp.255. ISBN 0-08-027116-2. (Pergamon: 1982.) £38, \$87.50.
BENGTSSON, L., GHIL, M. and KÄLLÉN, E. (eds). Dynamic Meteorology: Data Assimilation Methods. Pp.339. ISBN 3-540-90632-0. (Springer-Verlag: 1981.) Pbk DM44, \$20,50.

WADDELL, K. M. et al. Hydrologic Reconnaissance of the Wasatch Plateau-Book Cliffs Coal-Fields Area, Utah. Geological Survey Water Supply, Paper 2068. Pp.45 plus loose maps. (no ISBN) (US Government Printing Office, Washington: 1981.) Pbk np.

WOLFF, G. T. and KLIMISCH, R. L. (eds). Particulate Carbon Atmospheric Life Cycle. Proceedings of an International Symposium held October 1980 at the General Motors Research Laboratories, Warren, Michigan. Pp.411. ISBN 0-306-40918-6. (Plenum: 1982.) \$49.50.

Biological Sciences

ADRIAN, R. H. et al. (eds). Reviews of Physiology, Biochemistry and Pharmacology, Vol. 92. Pp.223. ISBN 3-540-11105-0. (Springer-Verlag: 1982.) DM88, \$41.

AKOYUNOGLOU, G. (ed.). Photosynthesis Vols. 1-6. Proceedings of the 5th International Congress on Photosynthesis, September 1980, Halkidiki, Greece. Pp.169 each vol. ISBN 0-86689-012-2 (6-Vol. set.) (Balaban International Science Services, Philadelphia: 1981.) Np.

ANSARA, A. et al. (eds). Sex Differences in Dyslexia. Pp.196. Pbk ISBN 0474-7534. (The Orton Dyslexia Society, Maryland: 1981.) \$15

ANTONINI, E., ROSSI-BERNARDI, L. and CHIANCONE, E. (eds). Methods

in Enzymology. Vol. 76, Hemoglobins. Pp.874. ISBN 0-12-181976-0. (Academic: 1981.) \$69.

ARMSTRONG, E. and FALK, D. (eds). Primate Brain Evolution: Methods and Concepts. Proceedings of a satellite Symposium of the International Primatological Society Meeting held July 1980 in Turin, Italy, and of a Symposium at the Annual Meeting of the American Association of Physical Anthropologists, held April 1980 in Niagara Falls, New York. Pp.332, ISBN 0-306-40914-3. (Plenum: 1982.) \$39.50.

AYRES, P.G. (ed.). Effects of Disease on the Physiology of the Growing Plant. Society for Experimental Biology Seminar Series, 11. Pp.228. Hbk ISBN 0-521-23306-2; pbk ISBN 0-521-29898-9. (Cambridge University Press: 1982.) Hbk £20; pbk £8.95.

BARRETT, P.H., WEINSHANK, D.J. and GOTTLEBER, T.T. (eds). Concordance to Darwin's Origin of Species, 1st Edn. Pp.834. ISBN 0-8014-1319-2. (Cornell University Press: 1982.) £27, \$48.10.

BEUMONT, P.J.V. and BURROWS, G.D. (eds). Handbook of Psychiatry and Endocrinology. Pp.464. ISBN 0-444-80355-6. (Elsevier Biomedical: 1982.) \$119, Dfl.256.

BLANDAU, R.J. (ed.). Morphogenesis and Malformation of the Skin. March of Dimes Birth Defects Foundation Birth Defects: Original Article Series, Vol.17. No.2, 1981. 6th International Workshop held at Lake Wilderness, Washington, September 1980. Pp.286. ISBN 0-8451-1042-X. (Alan R. Liss, New York: 1981.)£30, DM 132.

BRONNER, F. and PETERLIK, M. (eds). Calcium and Phosphate Transport Across Biomembranes. Based on an International Workshop on Calcium and Phosphate Transport Across Biomembranes held in Vienna, Austria, March 1981. Pp.300. ISBN 0-12-135280-3. (Academic: 1981.) \$28.

BROUWER, R. et al. (eds). Structure and Function of Plant Roots. Developments in Plant and Soil Sciences, Vol.4. Proceedings of the 2nd International Symposium held in Bratislava, Czechoslovakia, September 1980. Pp.423. ISBN 90-247-2510-0. (Martinus Nijhoff, The Hague: 1981.) Dfl. 150, \$65.

HUMAIN TOXICOLOGY

 $^{\prime\prime}_{O, \Lambda}$

An International Journal

Published Quarterly

VOLUME 1 NUMBER 2 Available April 1982

Contents

Radiation Carcinogenesis - What Risk? - P. N. Plowman

Uranium in Bone: Metabolic and Autoradiographic Studies in the Rat -N. D. Priest et al.

Assessment of Lead Intakes and Dose-response for a Population in Ayr Exposed to Plumbosolvent Water Supply -J. Sherlock et al.

Non-occupational Exposure to Pentachlorophenol: Clinical Findings and Plasma-PCI concentrations in Three Families -B. Sangster et al.

Induction of Hamster Hepatic Peroxisomal β -oxidation and Peroxisome Proliferation-associate 80000 mol wt Polypeptide by Hypolipidemic Drugs – M. K. Reddy et al.

Toxic Hepatitis due to Benzo-pyrone – P. Faurschou

Comparison of the Inhibitory Action of Delta-9-tetrahydrocannibinol and Petroleum Spirit Extrae of Herbal Cannabis on Human Sperm Motility – C. Y. Hong et al.

Effect of Pesticide Exposure on Human Microsomal Enzyme Induction -R. Uppal et al.

Teratogenicity and Perinatal Toxicity of Cadmium: a Review - N. G. Carmichael et al.

Oxalic Acid, Epsom Salt and the Poison Bottle: an Historical Review - W. A. Campbell.

STOP PRESS

VOLUME 1 NUMBER 3

Available in June 1982, and will be devoted to the subject of solvent abuse. Amongst the papers in Volume 1, Number 4, will be a study of sodium bromide in the human endocrine system; drug related acute medical admissions; and a study of the hazards of household cleaning products. This issue will be available in

October 1982.

Circle No.42 on Reader Service Card.
